The low-lying structure of $^{188,190,192}$W has been studied following $\beta$ decays of the neutron-rich mother nuclei $^{188,190,192}$Ta produced following the projectile fragmentation of a 1-GeV-per-nucleon $^{208}$Pb primary beam on a natural beryllium target at the GSI Fragment Separator. The $\beta$-decay half-lives of $^{188}$Ta, $^{190}$Ta, and $^{192}$Ta have been measured, with $\gamma$-ray decays of low-lying states in their respective W daughter nuclei, using heavy-ion $\beta$-$\gamma$ correlations and a position-sensitive silicon detector setup. The data provide information on the low-lying excited states in $^{188}$W, $^{190}$W, and $^{192}$W, which highlight a change in nuclear shape at $^{190}$W compared with that of lighter W isotopes. This evolution of ground-state structure along the W isotopic chain is discussed as evidence for a possible proton subshell effect for the $^{190}$ region and is consistent with maximization of the $\gamma$-softness of the nuclear potential around $N \sim 116$.

DOI: 10.1103/PhysRevC.80.064308 PACS number(s): 21.10.–k, 23.40.−s, 27.80.+w, 29.38.Db

I. INTRODUCTION

Nuclei with $A \sim 190$ for the elements between Hf ($Z = 72$) and Pt ($Z = 78$) exhibit a wide variation of nuclear structural properties, including well-deformed prolate shapes with rotational band structures [1]. K-isomeric states associated with axial symmetry in a deformed nuclear potential [2], and shape transitions across isotopic and isotonic chains [3, 4]. The evolution from axially symmetric deformed prolate shapes around the valence maximum nucleus at $^{170}$Pd [5] toward spherical, single-particle–like excitations close to the doubly magic nucleus $^{208}$Pb is predicted to pass through a region of triaxial $\gamma$-soft and oblate nuclei [6–8]. Nuclei that are predicted to lie on the boundary between regions of prolate and oblate deformation have been described by Jolie and Linneman as prolate-oblate phase-transitional systems [9]. The phase-transitional region between axially symmetric, deformed prolate and oblate shapes is also relevant to the limits of geometric symmetry within the interacting boson model (IBM) [10–13]. Platinum isotopes with $N = 116$ and 118 represent the best cases thus far for the experimental realization of the $O(6)$ symmetry limit of the IBM, which can be associated with a nuclear potential that is flat in the triaxial degree of freedom [14–16].

Evidence of increased $\gamma$-softness in the nuclear potential can be inferred from a number of simple experimental signatures. These signatures include a decrease in the excitation energy of the second $I^\pi = 2^+$ state [17] relative to the yrast $I^\pi = 2^+$ state and a reduction in the ratio of the excitation...
energies of the yrast $I^+ = 4^+$ and $2^+$ states, $R(4/2)$, compared
to the perfect axial rotor limit of 3.33. Evidence for such
behavior has been reported in a number of nuclei in this region,
including $^{192}$Os [18] and $^{194,196}$Pt [15,19].

One focus of the current work is to extend the spectral
knowledge of heavy, neutron-rich nuclei, with the specific aim
of studying the predicted evolution from prolate-deformed,
through $γ$-soft, to oblate-deformed shapes in neutron-rich tungsten
($Z = 74$) isotopes [7].

The heaviest stable tungsten isotope is $^{186}$W. Experimental
information on the neutron-rich isotopes of tungsten
with $N \geq 116$ is sparse because of the neutron-rich nature
of these systems. To investigate the change of structure
with increasing neutron number and the expected evolution
toward a more $γ$-soft and possibly oblate shape, the nuclei
of interest must be studied by either deep-inelastic collisions
[20–22] or projectile fragmentation reactions. Prior to this
work, the heaviest even-$N$ tungsten isotopes for which even
the most rudimentary spectral information had been reported
were $^{188}$W and $^{190}$W. In-beam spectroscopy of $^{188}$W
was studied previously using deep-inelastic [22] and two-nucleon
transfer reactions [23], which provided information on the
structure of the yrast sequence up to a spin of $8\hbar$. Transitions
populating the ground-state band of $^{190}$W were identified
via isomer-delayed $γ$-ray spectroscopy following relativistic
projectile fragmentation of a $^{208}$Pb beam [24–26]. The inferred
$R(4/2)$ value for $^{190}$W showed a sudden decrease in value
compared to the systematics in the region [24].

The present work primarily investigates the low-lying
nuclear structure of $^{188}$W, $^{190}$W, and $^{192}$W following $β$-delayed
spectroscopy of their mother nuclei, $^{188}$Ta, $^{190}$Ta, and $^{192}$Ta,
respectively. The data confirm the previously reported $R(4/2)$
value in $^{190}$W and also provide evidence for the observation
of the second $2^+$ state in this nucleus. The excitation energy
of the yrast $2^+$ state in $^{190}$W is also reported for the first time
in the current work. Preliminary results from this study have
been reported in a series of conference papers [27–29]; this
article provides the complete analysis of this work.

II. EXPERIMENTAL DETAILS

The nuclei of interest were produced following projectile
fragmentation reactions between a primary beam of
$^{208}$Pb impinging on a natural beryllium target of thickness
2446 mg/cm$^2$. The 1 GeV/nucleon beam was provided by the
SIS-18 heavy-ion synchrotron at GSI, Germany, with primary
beam intensities of up to $10^9$ ions/spill. The duration of each
primary beam spill was approximately 1 s with a typical
repetition period of 15–20 s. The secondary fragmentation
reaction residues were separated and identified event-by-event
using the GSI Fragment Separator (FRS) [30], operated
in monochromatic mode with an aluminum wedge-shaped
degradator positioned in the intermediate focal plane. Two
specific FRS settings were used in the current work, one
centered on fully stripped (i.e., $Q = Z$) ions of $^{190}$Ta and the
second centered on fully stripped $^{192}$Ta ions. Table I gives a
summary of the experimental parameters for the FRS in these
two settings.

### TABLE I. Experimental parameters for the two FRS settings studied in the current work.

A. Detector configuration at the FRS focal plane

A schematic of the experimental configuration used in the
current work is shown in Fig. 1. The secondary ions were
implanted into the RISING active stopper, which consisted of a series of double-sided silicon strip detectors (DSSSDs; see Refs. [28,31] for details). In the current work, the stopper configuration was positioned as shown in Fig. 1 and consisted of three 5 cm $\times$ 5 cm $\times$ 1 mm DSSSDs [32], each with 16 individual 3-mm-width strips on the front and back faces. The DSSSDs were used to determine the position of the implanted ion and to correlate it with its subsequent $β^-$ decay detected in the same or neighboring pixels of the DSSSD.

The correlation of low-energy (typically hundreds of keV) $β$ particles with significantly higher energy (typically a few GeV) implanted ions was afforded by the use of Mesytec semilogarithmic preamplifiers applied to the energy outputs of the DSSSDs [31]. These preamplifiers allowed a linear

![FIG. 1. Schematic of the detector configuration at the final focus of the GSI FRS for the current work. Three of the possible six positions (black boxes) in the active stopper were occupied by DSSSDs in this particular experiment. MW = multwire position detectors; Sci = plastic scintillator detectors; MUSIC = multiple sampling ionization chamber detectors. The number 4 corresponds to the detectors being placed at the final focus (i.e., after the fourth dipole magnet) of the GSI FRS. The secondary ions are transmitted from left to right on this schematic.](image-url)
amplification of the DSSSD signal for energies of up to 10 MeV, whereas a logarithmic amplification range was used for implantation energies of between 10 MeV and 3 GeV. The linear region of the preamplifier response was calibrated using the monoenergetic internal conversion electrons emitted using a standard $^{207}$Bi calibration source, which yielded a measured energy full width at half maximum (FWHM) of 20 keV at 980 keV and a minimum detection threshold of approximately 150 keV. This level of electron energy resolution was used to select delayed internal conversion electron lines following decays that were observed in other FRS settings from the same experiment (for example, in the internal conversion decay of a long-lived isomer in $^{205}$Au [33]). For the logarithmic portion of the preamplifier energy response, simulated signals from a pulser were used for the initial energy calibration, which was then checked by comparing the experimental data to simulations from the LISE3 code [34,35].

The active stopper was viewed by the stopped RISING $\gamma$-ray spectrometer array, which consists of 15 seven-element germanium cluster detectors with a measured total photopeak efficiency of $\sim 15\%$ at 662 keV [36,37]. Previously, the RISING array has been used to detect $\gamma$-ray transitions emitted following the decay of isomeric states in secondary fragments produced by projectile fragmentation and fission, using the techniques described in Refs. [24,25,38–42]. This experiment represents the first time that the RISING array was also used to correlate $\gamma$-ray transitions arising from the decays of states populated following the $\beta$ decay of secondary fragmentation products.

**B. Data reduction and particle identification process**

The identification of the projectile fragments was based on the time-of-flight (TOF) position and energy loss techniques described in Ref. [43]. The TOF in the second stage of the FRS was determined by measuring the time difference between the ions passing between two plastic scintillators mounted (i) before the degrader at the intermediate focal plane (after region S2) and (ii) at the final focal plane (after region S4). Two multiwire proportional chambers and two multiple sampling ionization chambers (MUSICs) provided position determination and energy loss information of the fragments at the final focal plane, respectively. The secondary ions of interest were then slowed down in a variable-thickness aluminum degrader (see Table I) before coming to rest in the RISING active stopper. Two plastic scintillators were placed before and after the active stopper to act as veto detectors for reactions in the final degrader and to remove events that produced light particles from nuclear reactions in the final degrader.

**1. Charge-state selection of secondary ions**

Charge-state anomalies in the transmitted secondary ions can cause problems with particle identification and the subsequent tagging of a $\beta$ decay from specific neutron-rich isotopes. In particular, hydrogen-like (i.e., $q = Z - 1$) ions of a given element can have a similar mass-to-charge ratio, $A/q$, as fully stripped ($q = Z$) ions. Thus, heavier neutron-rich isotopes of the same element can cause problems in the selection process. Such so-called $A/q$ anomalies can be partially resolved using the technique described in Ref. [43]. The difference in the magnetic rigidity of the ions, $B\rho$, before and after the intermediate focal plane degrader can be used to estimate the energy loss of the transmitted ions. This value can be correlated with the measured energy loss of the same ions in the two MUSICs at the final focus of the FRS to give loci of ions associated with different changes in charge state through the first and second halves of the FRS [30,37]. Niobium foils were placed after the target and the intermediate degrader to improve the atomic electron stripping efficiency. The ions transmitted through the FRS degrader were distributed into three main charge-state groups: (i) The group in which $\Delta q = 0$ is assumed to include predominantly ions that are fully stripped in both halves of the FRS. We note that there is a finite probability that the $\Delta q = 0$ condition could be satisfied by ions that are hydrogen-like in both halves of the FRS. However, the expected charge-state distributions for the ions using the GLOBAL code [44] suggest that the transmission of such events is highly suppressed compared to the fully stripped species. (ii) The group $\Delta q = +1$ is assumed to include predominantly ions that are fully stripped in the first part of the FRS and hydrogen-like ions (i.e., with one attached electron) in the second half of the FRS (i.e., after the intermediate focal plane degrader). (iii) The group $\Delta q = +2$ involves predominantly helium-like ions (two electrons) in the second half of the FRS and fully stripped in the first half. The GLOBAL code [44] gives a prediction that 96.7% of the $^{190}$Ta ions were fully stripped in the first half of FRS and 81.7% in the second half. Figure 2 shows the charge-state change groups of the transmitted ions by plotting the energy loss in a MUSIC detector versus energy loss in the intermediate degrader.

![FIG. 2. (Color online) The identification of the three charge-state change groups determined using the energy loss in the intermediate degrader and the MUSIC detector at the final focal plane of the FRS. These data are taken from both the $^{190}$Ta- and $^{192}$Ta-centered settings. The lower group of $\Delta q = 0$ corresponds predominantly to the fully stripped charge-state transmitted through the FRS (i.e., fully stripped ions in both the first and second halves of the FRS).](image-url)
2. Particle identification

The particle identification procedure was based on selecting the ions with $\Delta q = 0$, as illustrated in Fig. 2. Figure 3 shows the particle identification plot for $\Delta q = 0$ ions in terms of the atomic number, $Z$, as derived from the measured energy loss of the fragments in the MUSIC detector, versus the measured TOF in the second half of the FRS, which is related via the magnetic rigidity to the mass-over-charge ratio of the transmitted ions.

A two-dimensional matrix of detected $\gamma$-ray energies, as measured by the RISING array, versus their detection time relative to the signal from the heavy ion passing through the scintillation detector (Sci41) was created for all identified species in Fig. 3. The germanium $\gamma$-ray timing signal was recorded using the XIA DGF modules for each germanium channel, which gave an absolute time measurement with a resolution of 25 ns (see Refs. [37–41] for details). $\gamma$-rays from decays of previously reported isomeric states were used as internal checks on the particle identification procedure and to provide an independent validation of the $\gamma$-ray energy and timing measurement calibrations. Figure 4 shows selected $\gamma$-ray energy spectra and associated decay curves corresponding to $\gamma$-ray decays from isomeric states identified in the current work. Decays from the previously reported isomers in $^{188}$Ta, $^{190}$W, $^{192}$Re, and $^{190}$Re [25] are all clearly identified.

The current data also show evidence for isomeric states in $^{187}$Hf, $^{189,190}$Ta, and $^{191}$W. Evidence for the decays in $^{189}$Ta and $^{191}$W was previously reported in a conference proceeding from our Collaboration [45] following a survey of the region using the projectile fragmentation of a $^{208}$Pb beam with RISING and a passive stopper. The current data confirm these observations. In addition, previously unreported isomeric decays in $^{187}$Hf

We note that the data from the current work on the isomeric decay in $^{190}$W do not show any clear evidence for the 591 keV transition reported in Refs. [24,25]. This is discussed further in Ref. [26].

and $^{190}$Ta have been identified for the first time in the current work.

C. Implant-decay correlation technique

The technique of correlating the implanted ions with their subsequent $\beta^-$ decay is based on the identification of the implantation position in the active stopper and the time of correlation between the implanted ion and subsequent $\beta^-$ particle in the same or neighboring pixels of the DSSSD. The FRS was operated in monochromatic mode [46] in this experiment, which had the effect of distributing the implanted ions across a relatively wide area on the active stopper silicon detectors. This approach was required so that the probability of having multiple implantations of nuclei in the same pixel within a typical correlation time would be minimized. The use of the monochromatic mode also had the advantage of minimizing the range distribution of ions of a given species within the active stopper; thus, in general, selected isotopes of interest were stopped in a single layer of a given DSSSD. The radioactive ions were implanted in the DSSSD, with the implantation strip positions determined and an absolute measurement of the implantation time made via a digital, absolute time stamp. A valid implanted event was selected with the criterion that it produced a high-energy signal in the active stopper ($>10$ MeV) using the logarithmic region of the preamplifier response. Figure 5 shows two-dimensional position histograms of the implantations within one of the DSSSDs for $^{188}$Ta, $^{190}$W, and $^{192}$Re from the $^{190}$Ta setting.

The strip position, energy deposited, and time stamp for $\beta^-$-decay signals in the DSSSD were correlated with the most recent implantation signal in the active stopper and the time of correlation between the implanted ion and subsequent $\beta^-$ particle in the same or neighboring pixels of the DSSSD. The $\beta^-$-delayed $\gamma$ rays associated with these events are shown in Fig. 7, which provides spectral information on the daughter nuclei, $^{188}$W, $^{190}$W, and $^{192}$W. Implant-$\beta^-$ time differences of up to 100, 30, and 15 s for $^{188}$Ta, $^{190}$Ta, and $^{192}$Ta, respectively, were used in this analysis. These $\gamma$-ray spectra have all had random, normalized $\gamma$-ray spectra subtracted from them, with the random spectra generated from long correlation times after the implantation and normalized to the time range of the original time gate. The insets of Fig. 7 show the time spectra associated with $\beta^-$ decays of $^{188}$Ta, $^{190}$Ta, and $^{192}$Ta, gated on discrete $\gamma$-ray lines identified in the tungsten daughter nuclei. The quoted decay half-lives were determined using a single-component exponential decay with a least-squares-fit minimization method and assuming a constant background level. A summary of the results from this $\gamma$-ray analysis for the decays identified in $^{188}$W, $^{190}$W, and $^{192}$W in the present work is given in Table II.

A. Decay of $^{188}$Ta to $^{188}$W

Figure 7(a) shows discrete transitions at $\gamma$-ray energies of 143, 297, and 434 keV following the $\beta^-$ decay of $^{188}$Ta to excited states in $^{188}$W. A half-life of 19.6(20) s for this $\beta^-$-decaying...

$^a$Calculated assuming the extremum of a pure $E2$ multipolarity for the $2^+_1 \to 2^+_1$ decay.

$^b$Extrapolated value, taken from Ref. [48].

A state in $^{188}$Ta was deduced in the current work [see the inset in Fig. 7(a)].$^2$

These $\gamma$-ray energies correspond to previously observed decays from the first three excited states in the ground-state band of $^{188}$W, reported following in-beam studies using both deep-inelastic reactions [22] and two-neutron transfer reactions [23]. By contrast, the transition from the yrast 8$^+$ state in $^{188}$W ($E_\gamma = 554$ keV) as reported in Ref. [23] is not apparent in this spectrum. $\gamma$-ray energy peaks at 184, 204, and 401 keV are also identified in the $\beta$-delayed spectrum. These transitions were reported by Lane et al. [49] following the decay of an isomeric state in $^{188}$W, with a lifetime in the 100-ns regime. The current work does not have sufficient statistics for a $\gamma-\gamma$ coincidence analysis of the decays from this isomer.

The log $ft$ values were calculated assuming ground-state mass values taken from Ref. [50]. For the $^{188}$Ta decay, the log $ft$ value was estimated assuming a direct $\beta^-$-feeding branch to the yrast $I^{\pi} = 6^+$ state in $^{188}$W. It should be noted, however, that the observation of discrete transitions associated with the isomer decay branch reported by Lane et al. suggests some degree of competition in the direct feeding through a parallel branch in $^{188}$W. From the observed $\gamma$-ray intensities in Fig. 7(a), an estimate of the direct $\beta$ feeding to the yrast $I^{\pi} = 6^+$ state has been made, which in turn has been used to extract a value for log $ft$ for the decay of $^{188}$Ta to the yrast 6$^+$ state in $^{188}$W, given in Table II.$^3$ There is no evidence

$^2$Note that this discussion assumes that a single $\beta$-decaying state is observed in the present work. The presence of two parallel, low-lying, $\beta$-decaying states in $^{188}$Ta with similar half-lives cannot be ruled out in the current work.

$^3$Because the complete feeding intensity into the tungsten daughter is not established in the current work, we note that the log $ft$ values given in Table II should be regarded as lower limits rather than precise values.
in the current work that the decays from the reported isomer feed the $I^\pi = 6^+$ yrast state in $^{188}$W. Accordingly, we assume that the $\beta^-$-decay feeding from the decay of $^{188}$Ta leads to two parallel cascades of $\gamma$ rays with 53% of direct feeding to the yrast $I^\pi = 6^+$ state and the remainder feeding to the isomeric state. Under these assumptions, it is possible to derive a lower limit for the log $\beta^+$ value of 5.82(20) from the direct $\beta^-$-decay transition to the $I^\pi = 6^+$ state from the measured half-life of $^{188}$Ta of 19.6(20) s.

B. Decay of $^{190}$Ta to $^{190}$W

The $\beta$-delayed $\gamma$-ray spectrum for transitions in $^{190}$W is shown in Fig. 7(b). The previously reported isomeric state in $^{190}$W [24–26] was also directly populated via projectile fragmentation in the current work, as shown in Fig. 4. Following population by the $\beta^-$ decay of $^{190}$Ta, two discrete $\gamma$-ray lines at energies of 207 and 357 keV are observed, establishing these as the decays from the yrast states with $I^\pi = 2^+$ and $4^+$, respectively, in $^{190}$W. A $\gamma$-$\gamma$ coincidence analysis was also performed with the data from this experiment on the isomer-delayed transitions in $^{190}$W, which confirmed the mutually coincident nature of the 207- and 357-keV transitions (see Fig. 8).

In addition to these previously reported transitions in $^{190}$W, a transition at 247 keV is also observed in the $\beta$-delayed coincidence spectra following the decay of $^{190}$Ta. This transition is interpreted as arising from the decay of the $2^+_2$ state in $^{190}$W, which feeds directly into the yrast $I^\pi = 2^+$ state. The limited statistics in the current $\beta$-delayed data preclude a $\gamma$-$\gamma$ coincidence analysis to prove the direct feeding of the 247-keV line into the yrast $I^\pi = 2^+$ state; however, this interpretation is made on the following basis: (i) There are no other $\gamma$-ray transitions of similar intensity present in the $^{190}$Ta correlated, $\beta$-delayed spectrum shown in Fig. 7(b); (ii) The 485-keV transition (which is assumed to decay from the $I^\pi = 6^+$ member of the $^{190}$W ground-state band [24–26]) is not apparent in the $\beta$-decay data. (Note that the population of the yrast $6^+$ state in $^{190}$W is observed following the isomeric decay of the same nucleus in the current work; see Fig. 8.) Thus, it is suggested that $I^\pi = 2^+$ is the most likely spin-parity assignment for this level. (iii) An $I^\pi = 4^+$ assignment would make the 454-keV state yrast, in which case it would have been expected to have been populated in the decay of the isomeric state previously reported in $^{190}$W, which it is not. An $I^\pi = 3^+$ assignment would imply that it is a collective state and built on the $I^\pi = 2^+$ bandhead of the $\gamma$-band, which can be ruled out on the basis of a lack of observation of a candidate for the required $3^+_\gamma \rightarrow 2^+_2$ transition. (iv) Assignments of either $1^+$ or $1^-$ at this energy in an even-even nucleus are inherently unlikely. The assumption of a $2^+_2$ assignment for this state is further strengthened by the observation of a weak transition at 454 keV energy in the $\beta$-delayed spectrum for transitions in $^{190}$W [see inset in Fig. 7(b)], which would represent the direct transition from the $2^+_2$ state to the $0^+$ ground state in $^{190}$W.

The preceding arguments, together with the measured intensities (see Table II) for the observed decays from the $4^+$ and $2^+$ yrast states at 564 and 207 keV, respectively, in Fig. 7(b) imply a spin of $3\hbar$ for the $\beta$-decaying state in $^{190}$Ta. The assumption of a spin of $3\hbar$ for the $\beta$-decaying state in $^{190}$Ta is consistent (assuming direct population) with the previously discussed $I^\pi = 2^+$ assignment for the 454-keV level.

Figure 9 shows the systematics of the low-lying states in even-even tungsten isotopes with $A = 180 \rightarrow 192$ including the proposed $2^+_2$ state in $^{190}$W. Such states in deformed nuclei usually are associated with the bandhead of the $K^\pi = 2^+\gamma$-vibrational band. We note that the assumption of the second $2^+$ state in $^{190}$W at an excitation energy of 454 keV is in line with the trend expected for this region, with the ongoing, systematic decrease in the energy of the $2^+_2$ state relative to the yrast $4^+$ states in this isotopic chain approaching the $N = 116$ isotope, $^{190}$W.
If it is assumed that the $\beta^-$ decay of the $^{190}$Ta ground state feeds only the 207, 454 and 564 keV levels, then the log $\beta$ values for the $\beta^-$ feeding of these levels given in Table II can be derived using the half-life measured in the present work and a $Q_{\beta^-}$ value of 5.634 MeV [50].

C. Decay of $^{192}$Ta to $^{192}$W

The $\beta$-delayed $\gamma$-ray spectrum showing transitions in $^{192}$W following the decay of $^{192}$Ta is shown in Fig. 7(c). A single $\gamma$-ray line at an energy of 219 keV is evident and is interpreted as arising from the yrast $2^+ \rightarrow 0^+$ transition in $^{192}$W. The decay half-life measurement for $^{192}$Ta gated on the 219-keV $\gamma$-ray photopeak is $2.2 \pm 0.7$ s. We note that 219 keV is almost the same energy as the $2^+ \rightarrow 0^+$ transition in the $N = 118$ isotope, $^{194}$Os $[E(2^+) = 218 \text{ keV}]$, and indeed the same, near-isospectral behavior is also evident for the $N = 116$ isotonic doublet $^{190}$W and $^{192}$Os $[E(2^+) \approx 207 \text{ keV}]$. The possibility that the 219-keV transition observed in the present work is the result of a misassignment of the $\beta$ decay of $^{194}$Re into $^{194}$Os can be discounted as this specific decay has also been studied in the same data set, with multiple other transitions observed resulting from decays from higher spin states in $^{194}$Os [27].

The likely spin of the decaying state in the $^{192}$Ta parent nucleus can be restricted to $1\hbar$ or $2\hbar$ on the basis of the expected $\beta^-$-decay selection rules and the lack of any apparent line associated with the $4^+ \rightarrow 2^+$ transition in $^{192}$W. However, it should be noted that, on the basis of the statistics in the current work as shown in Fig. 7(c), the possible population of higher spin states in the yrast cascade in $^{192}$W and thus a higher spin for the $\beta^-$-decaying state cannot be ruled out. From a comparison of the number of implants and associated $\beta^-$-$\gamma$-ray coincident event, there is no strong evidence of direct feeding from the $\beta^-$ decay of $^{192}$Ta to the ground state of $^{192}$W, although such a branch cannot be exclusively ruled out in the current work. The lower limit for the log $\beta$ value for this decay given in Table II assumes 100% feeding in the $\beta^-$ decay to the proposed yrast $I^\pi = 2^+$ state in $^{192}$W.

IV. DISCUSSION

A. Subshell closure for the $A \sim 190$ region?

The systematics of the energy ratio $R(4/2) = E(4^+)/E(2^+)$ is arguably the best indicator of changes in low-lying nuclear structure [17]. However, for the most exotic nuclei, often only the energy of the first $2^+$ state is known. In general, the energy of the first $2^+$ state has been shown to decrease as the number of the valence nucleons (and related quadrupole collectivity) increases [32]. This general trend is opposite to the magnitude of the energy ratio and, thus, the $1/E(2^+_1)$ systematics should follow behavior similar to that for the $R(4/2)$ ratio. Cakirli and Casten [53] have recently used these empirically derived observables to demonstrate evidence for subshell closures in different regions of the nuclear chart. They also noted that the behavior of the $R(4/2)$ and $1/E(2^+_1)$ observables appear to scale with each other in regions of shape evolution and that evidence of subshell closures can be seen in the appearance of a “bubble” in the evolution of such plots as a function of proton or neutron number.

The energy ratios in Fig. 10 show a gradual, systematic decrease in the value of $R(4/2)$ with neutron number from $^{182}$W$_{108}$ [$R(4/2) = 3.29$] to $^{188}$W$_{114}$ [$R(4/2) = 3.07$]. This is followed by a very dramatic decrease at the $N = 116$ isotone, $^{190}$W, for which the ratio drops to a value of $R(4/2) = 2.7$, approaching the triaxial-rotor limit of $R(4/2) = 2.5$. This gives rise to what appears to be the onset of the bubble effect described by Cakirli and Casten. With the data point for $^{192}$W from the current work, this behavior is even more dramatically demonstrated by the behavior of the $1/E(2^+_1)$ observable, as shown in Fig. 11, which shows the beginning of a gap/bubble pattern for the $A \sim 190$ region. Evidence for such a subshell effect or dramatic shape evolution with the addition or removal of two nucleons can also be seen from the difference

![Fig. 10](image1)

![Fig. 11](image2)
in \( R(4/2) \) between neighboring even-even isotopes; that is, 
\[
\delta R(4/2) = R(4/2)_{Z,N} - R(4/2)_{Z,N-2}
\]
[54]. Figure 12 shows this quantity for the Hf, W, Os, and Pt isotopes with neutron numbers ranging from the midshell at \( N = 104 \) up to \( N = 118 \). 

The value for \( \delta R(4/2) \) of greater than 0.3 between \(^{188}\)W and \(^{190}\)W represents one of the largest \( \delta R(4/2) \) differences in the entire Segré chart. This provides compelling evidence for a dramatic change in the ground-state structure for W isotopes in going from \( N = 114 \) to \( N = 116 \).

### B. Triaxial softness around \( N = 116 \)

Evidence for triaxial (or \( \gamma \)-soft) collective behavior in nuclei can be obtained by using a number of basic experimental observables. These include (i) \( R(2_2/2_1) \), the excitation energy ratio between the second and first spin-parity \( 2^+ \) states; (ii) the \( R(4/2) \) ratio; and (iii) the ratio of the reduced matrix probabilities between the second and the first \( 2^+ \) states and from the second \( 2^+ \) state to the ground state, \( R_2 = \frac{B(E2;2^+_2 \rightarrow 0^+_1)}{B(E2;2^+_1 \rightarrow 0^+_0)} \) [17]. The \( E(2^+_1) \) energy is expected to increase with increasing neutron number as the \( N = 126 \) shell closure is approached. This increase seems to be continued for the heavier tungsten isotopes using the data for the \( 2^+_1 \) energy in the \( N = 118 \) isotope, \(^{192}\)W, from the current work. This general behavior of a reduction in the energy ratio \( R(4/2) \) and parallel increase in the energy of the first \( 2^+ \) state in these isotopes is indicative of the expected reduction in quadrupole collectivity as the neutron number approaches the \( N = 126 \) closed shell.

The \( R(4/2) \) value in \(^{190}\)W can be explained as a general feature of a \( \gamma \)-soft potential. Jolie and Linnemann [9] suggested that the region of nuclei between \(^{180}\)Hf and \(^{200}\)Hg exhibits prolate-oblate deformations and phase-shape transitions between these two shapes. There have also been theoretical predictions of a ground-state/low-lying shape transition from prolate to oblate shapes in this mass region using a variety of mean-field models (see Ref. [7] and references therein). This phase transition occurs at the O(6) symmetry in the interacting boson approximation (IBA) [10–13]. It is useful to apply the IBA model to \(^{190}\)W, because it allows one to investigate the \( \gamma \) dependence of the potential appropriate for this nucleus. To study \(^{190}\)W, we used a simple, two-parameter IBA-1 Hamiltonian suitable for most collective nuclei. This Hamiltonian can be written as [55,56]

\[
H(\xi) = c \left[ (1 - \xi)\hat{n}_d - \frac{\xi}{4N} \hat{Q}^2 \cdot \hat{Q}^2 \right],
\]

where \( N \) is the number of valence bosons, \( \hat{n}_d = d^\dagger \cdot \hat{d} \), and \( \hat{Q}^2 = (s^\dagger \hat{d} + d^\dagger s) + \chi (d^\dagger \hat{d}) \).

This Hamiltonian has two parameters, \( \xi \) and \( \chi \), with an overall scaling factor. In this Hamiltonian, \( \xi = 0 \) gives a U(5) or a quadrupole vibrator spectrum (the \( \hat{n}_d \) term) while \( \xi = 1 \) gives a rotor (the \( \hat{Q} \cdot \hat{Q} \) term). In this latter case, one has an axial rotor for \( \chi = -\frac{\sqrt{2}}{2} \approx -1.32 \) and a \( \gamma \)-soft [O(6)] for \( \chi = 0 \). Intermediate values of \( \xi \) and \( \chi \) allow one to span a wide range of collective structures.

To use Eq. (1), a technique was used based on the orthogonal cross-contour method [57]. In this approach, one can place a nucleus in the symmetry triangle for the IBA by using a contour of constant values of a pair of observables. With the data available, we used \( R(4/2) \) and \( E(2^+_2) \). In the O(6) limit, \( E(2^+_2) = E(4^+_1) \) due to their common membership in the \( \tau = 2 \), O(5) multiplet. For any other situation, the IBA-1 Hamiltonian [55,56] of Eq. (1) gives \( E(2^+_2) > E(4^+_1) \). Therefore, it is impossible to obtain a precise fit for the \(^{190}\)W data, because the experimental values have \( E(2^+_2) < E(4^+_1) \).

Experimentally, \( R(4/2) = 2.72 \) for \(^{190}\)W. The contour for this value for \( N = 9 \) is shown in the inset of Fig. 13. To investigate the structure further, another observable is required, and so the \( E(2^+_2) \) values are calculated along the \( R(4/2) = 2.72 \) contour. The results for \( E(2^+_2) \) are compared with experimental value, as shown in Fig. 13.

The experimental value of \( R(4/2) \) is consistent with a \( \gamma \)-soft \([R(4/2) \approx 2.5 \) structure but does not establish it because a
value of 2.7 can also be obtained for an axially symmetric quasirotor, as seen in the inset of Fig. 13. Because the two parameters of the IBA-1 Hamiltonian of Eq. (1) cannot fit a $2^+_2$ energy as low as observed experimentally, the best fit is obtained for a $\gamma$-soft structure very close to O(6). The theoretical-level scheme obtained from this procedure is compared with the experimental data in Fig. 14.

From a consideration of O(6) and also of the IBA calculations on the right-hand side of Fig. 14, one characteristic feature is a staggering in the $\gamma$-band energies, and in particular a near degeneracy of the $3^+_1$ and $4^+_1$ levels. Experimentally identifying these levels would provide a good future test of these ideas.

The identification of a weakly populated peak at 454 keV energy in $^{190}$W suggests a direct transition from the $2^+_2$ state to the ground state $0^+$ in $^{190}$W. In the pure, idealized O(6) limit, such a transition is forbidden [10–13]; however, in realistic, finite nuclear systems, such hindered transitions have been observed. The statistics in the current work preclude an angular distribution analysis to establish the $M1/E2$ mixing ratio of the proposed, unstretched $(2^+_2 \rightarrow 2^+_1)$ transition in $^{190}$W ($E_{\gamma} = 247$ keV).

Another empirical quantity, which has been used to infer the prolate-oblate shape-transition regions, is the energy ratio $E(2^+_2)/E(2^+_1)$ [58]. Figure 15 shows a systematic of this ratio versus the neutron number of even-even Hf $\rightarrow$ Hg ($Z = 72 \rightarrow 80$) isotopes $N = 104 \rightarrow 120$. The figure shows an apparent maximization of the $\gamma$ softness for Os, Pt, and Hg at neutron number $N = 116$ in which the new data point for $^{190}$W from the current work is consistent with this trend.

An estimate of the value of the static or average triaxial deformation parameter, $\gamma$, can be extracted from the Davydov model [59] using the energy ratio $E(2^+_2)/E(2^+_1)$. Although the Davydov model represents an asymmetric nucleus with a rigid shape, this parameter can provide a simple prediction of a static $\gamma$ value that can be compared with the average $\gamma$ value associated with $\gamma$-soft potentials. The expression described in

![FIG. 14. Results of IBA-1 calculations for $^{190}$W and comparison with the experimentally measured low-lying energy levels for this nucleus.](image1)

![FIG. 15. (Color online) The ratio of the excitation energies of the $I^\pi = 2^+_2$ and $I^\pi = 2^+_1$ states for heavy even-even neutron-rich nuclei with $N = 104 \rightarrow 120$. These data are taken from Ref. [51] and the current work for $^{190}$W.](image2)

![FIG. 16. (Color online) Empirically deduced $\gamma$ values for heavy Hf $\rightarrow$ Hg even-even neutron-rich nuclei with $N = 104 \rightarrow 120$ using Eqs. (2) and (3) of the Davydov model (see text for details).](image3)

![FIG. 17. (Color online) Systematics of the excitation energy difference between the $I^\pi = 2^+_1$ and $I^\pi = 4^+$ states for the even-even Hf $\rightarrow$ Hg nuclei as a function of the neutron numbers for $N = 104 \rightarrow 120$. These data are taken from Ref. [51] and the present work.](image4)
Ref. [17] is used to extract the $\gamma$ value as follows:

$$
\frac{E(2^+_2)}{E(2^+_1)} = \frac{[1 + X]}{[1 - X]},
$$

(2)

where

$$
X = \sqrt{1 - \frac{8}{9} \sin^2(3\gamma)}.
$$

(3)

Therefore, when $X = 1$ (i.e., for $\gamma = 0^\circ$), the energy ratio $E(2^+_2)/E(2^+_1) \to \infty$, whereas for $X = 1/3$, $\gamma = 30^\circ$. For $^{190}$W the ratio of $E(2^+_2)/E(2^+_1)$ is equal to 2.19, leading to a value of $\gamma \approx 27^\circ$. Figure 16 shows the $\gamma$ values extracted for the even-even Hf $\to$ Hg isotopes with $N = 104 \to 120$ using Eqs. (2) and (3). The maximum $\gamma$-value appears to be reached at $N = 116$ for W, Os, and Hg.

A second quantity used to infer prolate-oblate shape-transition regions is the energy difference between the $E(2^+_2)$ and $E(4^+_2)$ states [$58$]. According to Kumar [$60$], a negative value of $E(2^+_2) - E(4^+_2)$ (i.e., the second $2^+$ state lying lower in energy than the yrast $4^+$ state) is a good indicator of a region of prolate-oblate phase transition. Figure 17 shows this energy difference versus the neutron number for this region of interest. These systematics display similar characteristics to the $E(2^+_2)/E(2^+_1)$ systematics shown in Fig. 15. The neutron number $N = 116$ again appears to be associated with maximum $\gamma$ softness for the low-lying states in the Os, Hg, and possibly W isotopic chains.

In their recent theoretical studies of this region using a Skyrme Hartree-Fock plus BCS pairing approach, Sarriguren et al. [$7,61$] predicted that $^{190}$W lies on the near-critical point between prolate and oblate shapes in this region, with a prediction of a very shallow triaxial minimum for the ground-state shape with a predicted $\gamma = 25^\circ$. These authors also point out that neutron number $N = 116$ appears to be a “saddle point” for the the Yb, Hf, W, and Os isotopes with respect to maximum $\gamma$ softness at the transition between axially symmetric prolate and oblate ground states for $N \leq 114$ and $N \geq 118$, respectively.

Total Routhian surface (TRS) calculations using the prescription described in Ref. [62] for the ground-state configurations of $^{188,190,192}$W have been performed as shown in Fig. 18. The calculations predict an evolution from a prolate (albeit) $\gamma$-soft potential in $^{188}$W to a very $\gamma$-soft potential for $^{190}$W and $^{192}$W. Indeed, the very flat energy change associated with the $\gamma$ degree of freedom for $\beta_2 \approx 0.15$ can be linked to a clear predicted region of prolate/oblate shape coexistence associated with an $O(6)$-like potential.

V. CONCLUSIONS

The low-lying states of $^{188}$W, $^{190}$W, and $^{192}$W have been investigated following the $\beta^-$ decay of their tantalum mother nuclei populated in relativistic projectile fragmentation reactions. The results support the previously reported assignments for the first $2^+$ and $4^+$ states in $^{190}$W and provide candidates for decays from the second $2^+$ state in this nucleus and the first $2^+$ state in $^{192}$W. The results are consistent with the fact that $N = 116$ represents a maximum value of $\gamma$ softness in this region at the intersection between prolate and oblate deformations for lighter and heavier isotopes, respectively. A direct link between the emergence of a localized proton subshell closure at $Z \leq 74$ for $N \geq 116$ and the apparent maximum values of $\gamma$ softness around $N \sim 116$ is not clear at the present time.
