Abstract. We prove that the return time statistics of a dynamical system do not change if one passes to an induced (i.e. first return) map. We apply this to show exponential return time statistics in (i) smooth interval maps with nowhere-dense critical orbits and (ii) certain interval maps with neutral fixed points. The method also applies to (iii) certain quadratic maps of the complex plane.

1. Introduction
In the last few years, the study of return and hitting times has become an important ingredient for the statistical characterization of dynamical systems. A historical account of this approach can be found in the review paper [10] or in the introduction of [20], where an extended bibliography is also provided. To pose the problem in general terms, suppose that $T$ is a measure-preserving transformation of a measure space $(X, \mu)$ and $U_x \subset X$ is a neighbourhood of a point $x \in X$. The two questions which are the fundamental objects of investigation are as follows.
1. What is the probability distribution of the first hitting time of the set $U_x$ as $\mu(U_x) \to 0$?
2. What is the probability distribution of the first return time for points leaving from $U_x$ as $\mu(U_x) \to 0$?

For large classes of dynamical systems showing some sort of hyperbolic behaviour, the answers to these questions are surprisingly easy and universal. The probability distribution function, up to a suitable normalization, turns out to be the exponential 1-law $\exp(-t)$.

If $\tau_U(x)$ is the smallest integer $n$ such that $T^n(x) \in U$ (so $\tau$ stands for first hitting and for first return time), then both

$$
\mu \left( \left\{ x \in X ; \tau_U(x) \geq t/\mu(U) \right\} \right) \to e^{-t}
$$

and

$$
\frac{1}{\mu(U)} \mu \left( \left\{ x \in U ; \tau_U(x) \geq t/\mu(U) \right\} \right) \to e^{-t},
$$

as $\mu(U) \to 0$. After the works of Pitskel [36], Hirata [19] and Collet [11] at the beginning of the 1990s which focused essentially on uniformly hyperbolic dynamical systems, new developments have brought at least three improvements:

- the possibility to treat larger classes of systems, notably certain non-uniformly hyperbolic systems;
- the possibility to estimate the error to the asymptotic distribution which is closely related to the hyperbolic character of the transformation and to the influence of sets with short recurrence;
- the application of the exponential statistics to the computation of the fluctuations of repetition times in the Ornstein–Weiss formula for the metric entropy.

These improvements were the result of four new approaches. The first approach was originated by Galves and Schmitt [15] and was formulated in a probabilistic setting for systems satisfying a $\phi$-mixing condition. This approach was translated into the dynamical systems language by Haydn for Julia sets [16], by Paccaut [34] for a large class of non-Markovian maps of the interval and by Boubakri [4] for some Collet–Eckmann unimodal maps. Recently Abadi [2] extended it for $\alpha$-mixing stationary processes. The true probabilistic flavour of this technique led to the discovery of a close connection with the Ornstein–Weiss Theorem [33] on metric entropy and resulted in a proof of the log-normal fluctuations of the repetition times for Gibbs measures in [13] (see [22] for related results); see also [34] for further developments.

The second approach is due to Hirata et al [20]. First, for measure-preserving dynamical systems it quantifies the error to the asymptotic $\exp(-t)$ distribution giving precise bounds in terms of the mixing properties of the systems and of a sharp control of short recurrences (this last point is in itself an interesting subject suggesting the possibility to formulate a thermodynamics of return times [39, 40]). These bounds are then computed for a large class on non-uniformly hyperbolic maps of the interval in [20]. We use this method in the present paper to prove the exponential statistics for the class of Rychlik maps introduced in §3. A key observation in [20] allows us to link the statistics of hitting and return times quoted above, namely the distribution of the first return time is close to the exponential law if and only if it is close to the distribution of the first hitting time.

The third approach goes back to a probabilistic paper of Sevast’y'anov [41]. This approach was already used by Pitskel [36] in the context of Markov chains and
Axiom-A diffeomorphisms. The same scheme was applied by Haydn in [16] and [17] for equilibrium states on Julia sets, in the presence of a supremum gap in the Perron–Frobenius operator (namely, if $f$ is a Hölder continuous function on the Julia set of a rational map of degree at least 2, then $P(f) > \sup f$, where $P(f)$ is the topological pressure of $f$). The original technique of Sevast'yanov only allowed the convergence to the exponential 1-law to be proved. A recent work by Haydn and Vaienti [18] quantifies this technique and thus provides bounds for the error estimate in the case of rational maps and parabolic maps of the interval; such bounds improve all other existing bounds for the class of maps considered.

The last approach was introduced by Collet [12]; it is an application of Gumbel’s law for entrance times [14] to a large class of non-uniformly hyperbolic dynamical systems with exponential decay of correlations for which a tower satisfying Young’s conditions can be constructed [48, 49]. Collet has proven that the statistics of closest return to a given point are almost surely asymptotically Poissonian and gave the fluctuations for the nearest return to the starting point.

It is useful to remark at this point that the approaches we are describing also permit us to compute the probability distribution of successive visits to the set $U_x$: it gives, in all the cases where the exponential statistics hold, the Poisson distribution $(t^n/n!\,e^{-t})$, where $n$ is the number of visits of $U_x$.

In this paper we propose a new scheme which allows us to compute the asymptotic distributions for the first and successive return times, whenever these distributions are known on a subset endowed with an induced structure. Its interest lies in the fact that several non-uniformly hyperbolic systems admit around almost every point (with respect to the invariant measure) a neighbourhood where the first return map acts as the induced transformation and exhibits hyperbolic behaviour. The first application of our approach is for $C^2$ interval maps: we prove the exponential return time statistics under the additional hypothesis that the map preserves a conformal measure (see §4 for details) and that the closure of the orbit of the critical points has zero measure. Our result complements those given by Boubakri [4] and Collet [12], in the sense that, contrarily to them, the growth rate of the derivatives along the critical orbit plays no role in our theorem. It applies, for example, to the well-known Fibonacci map [28].

As a second example, we improve the exponential statistics for the parabolic map studied in [20]. In both cases, the first return map of the induced systems belongs to a class of piecewise monotonic maps of the interval (with countably many pieces), previously investigated by Rychlik; the induced measure shows the exponential decay of correlations with respect to the Rychlik map and this is the kind of hyperbolic behaviour which is sufficient to prove the exponential statistics for such maps.

In most of the approaches quoted above, the set $U_x$ shrinking to $\{x\}$ was chosen in the class of cylinders generated by some partition of the space. The exponential return time statistics around cylinders is what is needed to compute the fluctuations in the Ornstein–Weiss Theorem [39].

Instead of cylinders, one can also use balls for the sets $U_x$. The use of balls has a twofold interest. First, it enlarges the class of sets where we can check the recurrence of rare events, such as the entrance time (particularly from the perspective of numerical
simulations in physical situations; see for example [9] and [50]). Second, the behaviour of the return time in balls is strongly related to other statistical indicators, like local dimension and Lyapunov exponents, as shown in [40].

Balls instead of cylinders were used by Haydn [17] and Collet [12]. In this paper we prove the exponential statistics for Rychlik maps around balls. This improves the work of [34], where a particular class of Rychlik maps (the covering weighted systems introduced in [25]) and only cylinders around points were considered.

The general scheme proposed in this paper could, in principle, be applied to a wide class of dynamical systems for which the induced transformation enjoys exponential statistics; in particular, we think of rational maps of the Riemann sphere (an example is given in §5) and of billiards for which the induced structures, although not yet studied, seem however more accessible than the original systems.

As a final observation, we would like to point out the robustness of the exponential statistics, which persists in the non-hyperbolic systems covered in this paper. This confirms its central role in the characterization of recurrence for ergodic systems and motivates further analysis for larger classes of transformations, especially in dimensions greater than one and exhibiting singularities.

2. Statistics via inducing: an abstract theorem
Suppose that \((T, X, \mu)\) is an ergodic measure-preserving transformation of a smooth Riemannian manifold \(X\). Let \(\hat{X} \subset X\) be an open set. Furthermore, let \(\hat{T} : \hat{X} \to \hat{X}\) be the first return map. We denote the induced measure by \(\hat{\mu}\): the measure-preserving transformation \((\hat{T}, \hat{X}, \hat{\mu})\) is therefore ergodic†. For \(z \in X\), we denote by \(U_r(z)\) the ball of radius \(r\) centred at \(z\) and by \(\tau_{U_r(z)}\) (respectively \(\hat{\tau}_{U_r(z)}\)) the first return time of \(U_r(z)\) for \(T\) (respectively \(\hat{T}\)). For a \(\mu\) (respectively \(\hat{\mu}\)) measurable set \(A\) we denote by \(\mu_A\) (respectively \(\hat{\mu}_A\)) the induced measure on the set \(A\). We suppose that \((\hat{T}, \hat{X}, \hat{\mu})\) has return time statistics \(\hat{f}(t)\): i.e. for \(\hat{\mu}\)-almost every \(z \in \hat{X}\), there exists \(\varepsilon_z(r) \to 0\) such that

\[
\sup_{t \geq 0} \left| \hat{\mu}_{U_r(z)} \left( x \in U_r(z) : \hat{\tau}_{U_r(z)}(x) > \frac{t}{\hat{\mu}(U_r(z))} \right) - \hat{f}(t) \right| < \varepsilon_z(r).
\]  

(1)

Our main theorem of this section is that on \(\hat{X}\) the map \(\hat{T}\) obeys the ‘same’ statistical law as \(T\).

**Theorem 2.1.** If \(\hat{f}\) is continuous at 0, then there exists \(f : \mathbb{R}^+ \to [0, 1]\) such that \(N \overset{\text{def}}{=} \{ x : f \neq \hat{f} \}\) is countable and for \(\mu\)-almost every \(z \in \hat{X}\) and \(t \notin N\), there exists \(\delta_{z,t}(r) \to 0\) uniformly in \(t\) as \(r \to 0\) such that

\[
\left| \mu_{U_r(z)} \left( x \in U_r(z) : \tau_{U_r(z)}(x) > \frac{t}{\mu(U_r(z))} \right) - f(t) \right| < \delta_{z,t}(r).
\]  

(2)

In addition, if \(\hat{f}\) is continuous then the convergence is uniform in \(t\), which means there exists \(\delta_z(r) \to 0\) as \(r \to 0\) such that for all \(t \in \mathbb{R}^+\) and \(r > 0\), \(\delta_{z,t}(r) \leq \delta_z(r)\).

† We could weaken our assumptions by demanding that the map \(\hat{T}\) is ergodic instead of \(T\); the ergodicity of \(T\) is, however, recovered when \(X = \bigcup_{n=0}^{\infty} T^{-n} \hat{X}\).
Remark. The function \( \hat{f} \) (respectively \( f \)) is known to be decreasing and thus continuous everywhere except for an at most countable set of exceptional points. The set \( N \) is a subset of the points of discontinuity of \( \hat{f} \).

Proof. First of all, if \( \mu \) has an atom then \( \mu \) is supported on a periodic orbit, hence the result is trivial because in this case \( f(t) = \hat{f}(t) = 1 \) for \( t \leq 1 \) and 0 otherwise. We may assume then that \( \mu \) has no atoms, consequently \( \mu(U_r(z)) \to 0 \) as \( r \to 0 \) for all \( z \in \hat{X} \).

At first we suppose that \( z \in \hat{X} \) and assume that \( r \) is small enough so \( U_r(z) \subset \hat{X} \). Note that this implies \( \hat{\mu}_{U_r(z)} = \mu_{U_r(z)} \).

For \( x \in \hat{X} \), let \( n(x) \overset{\text{def}}{=} \tau_{U_r}(x) \) be the \( T \)-first return time of \( x \) to \( \hat{X} \). By Kac’s Theorem and the ergodicity of \( \hat{\mu} \), we have

\[
A_m(x) \overset{\text{def}}{=} \frac{1}{m} \sum_{i=0}^{m-1} n(\hat{T}^i x) \underset{m \to \infty}{\longrightarrow} c \overset{\text{def}}{=} \int_{\hat{X}} n(x) d\hat{\mu} = \frac{1}{\mu(\hat{X})} \tag{3}
\]

for \( \hat{\mu} \)-almost every \( x \in \hat{X} \). Let \( G \overset{\text{def}}{=} \{ x \in \hat{X} : \lim_{m \to \infty} A_m(x) = c \} \). Clearly \( \hat{\mu}(G) = 1 \).

For all \( x \in G \) and for all \( \varepsilon > 0 \), there exists \( m(x, \varepsilon) < \infty \) such that \( |A_m(x) - c| < \varepsilon \) for all \( m \geq m(x, \varepsilon) \). Let \( G_m \overset{\text{def}}{=} \{ x \in G : m(x, \varepsilon) < m \} \) where we have suppressed the obvious \( \varepsilon \) dependence on the set \( G_m \). We choose \( M \overset{\text{def}}{=} M(\varepsilon) \) such that \( \mu(G_M) > 1 - \varepsilon \).

By definition, \( \left| \sum_{i=0}^{m-1} n(\hat{T}^i x) - cm \right| < \varepsilon m \) for all \( m \geq M \) and all \( x \in G_M \).

Thus \( \hat{T}^m(x) = T^{m+s(x)}(x) \) for some \( s = s(x) \) with \( |s| < \varepsilon m \). It immediately follows that \( \tau_{U_r(z)}(x) = c \hat{\tau}_{U_r(z)}(x) + s \) with \( |s| < \varepsilon \hat{\tau}_{U_r(z)}(x) \) whenever \( \hat{\tau}_{U_r(z)}(x) \geq M \) and \( x \in G_M \).

Next we define

\[
\tilde{G}_M \overset{\text{def}}{=} \left\{ z \in G_M : \mu_{U_r(z)}(G_M) \underset{r \to 0}{\longrightarrow} 1 \right\}. \tag{4}
\]

By the Lebesgue Density Theorem, \( \hat{\mu}(\tilde{G}_M) = \hat{\mu}(G_M) \) and thus \( \hat{\mu}(\tilde{G}_M) > 1 - \varepsilon \).

For each \( z \in G_M \) there exists \( r(z, M, \varepsilon) > 0 \) such that \( \mu_{U_r(z)}(G_M) > 1 - \varepsilon \) for all \( r < r(z, M, \varepsilon) \). Thus if \( R > 0 \) is sufficiently small then \( \hat{\mu}(G_{M,R}) > 1 - \varepsilon \), where \( G_{M,R} \overset{\text{def}}{=} \{ z \in G_M : r(z, M, \varepsilon) > r \} \).

Let \( S \) be the set of points \( z \in \hat{X} \) for which \( \varepsilon_z(r) \to 0 \) as \( r \to 0 \). By assumption \( \hat{\mu}(S) = 1 \). Hence \( \hat{\mu}(G_{M,R} \cap S) = \hat{\mu}(G_{M,R}) > 1 - \varepsilon \).

Denote

\[
\mathcal{F}_{U_r(z)}(t) \overset{\text{def}}{=} \mu_{U_r(z)}(\{ x \in U_r(z) : \tau_{U_r(z)} > t / \mu(U_r(z)) \}),
\]

\[
\hat{\mathcal{F}}_{U_r(z)}(t) \overset{\text{def}}{=} \hat{\mu}_{U_r(z)}(\{ x \in U_r(z) : \hat{\tau}_{U_r(z)} > t / \hat{\mu}(U_r(z)) \}),
\]

and set \( B_{U_r(z)}(M) = \{ x \in U_r(z) : \hat{\tau}_{U_r(z)}(x) > M \} \).

Assume additionally that \( z \in G_{M,R} \cap S \). The limiting distribution \( \hat{f}(t) \) is continuous at 0 and \( \hat{f}(0) = 1 \), hence if \( r \) is sufficiently small

\[
\mu_{U_r(z)}(B_{U_r(z)}(M')) = \hat{\mu}_{U_r(z)}(B_{U_r(z)}(M')) \leq 1 - f(M \hat{\mu}(U_r(z))) + \varepsilon_z(r) < \varepsilon.
\]
Thus for all $t \in [0, \infty)$,

$$F_{U_r(t)}(t) \leq \mu_{U_r(t)}\left(G_{M,R}^c \cup B_{U_r(t)}(M)^c\right) + \mu_{U_r(t)}\left(G_{M,R} \cap B_{U_r(t)}(M) \cap \left\{ x : \tau_{U_r(t)}(x) > \frac{t}{\mu(U_r(z))}\right\}\right) \leq \mu_{U_r(t)}\left(G_{M,R}^c\right) + \mu_{U_r(t)}\left(B_{U_r(t)}(M)^c\right) \leq 2 \varepsilon + \hat{F}_{U_r(t)}\left(\frac{t}{1 + \varepsilon/c}\right).$$

A similar computation with $1 - F_{U_r(t)}(t) = \mu_{U_r(t)}\left(\tau_{U_r(t)} \leq \frac{t}{\mu(U_r(z))}\right)$ yields

$$\hat{F}_{U_r(t)}\left(\frac{t}{1 - \varepsilon/c}\right) - 2 \varepsilon \leq F_{U_r(t)}(t) \leq \hat{F}_{U_r(t)}\left(\frac{t}{1 + \varepsilon/c}\right) + 3 \varepsilon. \quad (5)$$

For $r$ sufficiently small, $\varepsilon_z(r) < \varepsilon$. Thus inequality (5) implies

$$-3 \varepsilon + \hat{f}\left(\frac{t}{1 - \varepsilon/c}\right) \leq F_{U_r(t)}(t) \leq \hat{f}\left(\frac{t}{1 + \varepsilon/c}\right) + 3 \varepsilon. \quad (6)$$

Define

$$\delta_t(z) \overset{\text{def}}{=} \max\left\{|\hat{f}(t) - \hat{f}\left(\frac{t}{1 - c^{-1}\varepsilon}\right)|, |\hat{f}(t) - \hat{f}\left(\frac{t}{1 + c^{-1}\varepsilon}\right)|\right\}. \quad (7)$$

For each point $t$ of continuity of $\hat{f}$, the function $\delta_t(\varepsilon) \to 0$ as $\varepsilon \to 0$. Combining (6) and (7) yields

$$|F_{U_r(t)}(t) - \hat{f}(t)| \leq 3 \varepsilon + \delta_t(\varepsilon). \quad (8)$$

We just showed that for any $\varepsilon > 0$, there exists a set $G(\varepsilon)$ with $\hat{\mu}(G(\varepsilon)) > 1 - \varepsilon$ and a real number $R(\varepsilon) > 0$ such that for all $z \in G(\varepsilon)$, inequality (8) holds whenever $r < R(\varepsilon)$. The conclusion of the theorem for $\mu$-almost every $z \in \hat{X}$ follows from the remark that $\mu$-almost every $z \in \hat{X}$ is contained in the set of full measure $\bigcap_{n>0} \bigcup_{m>n} G(1/m)$.

Finally, we want to prove the uniform convergence in $t$ in the case $\hat{f}$ is continuous. Since $\hat{f}(t) \to 0$ as $t \to \infty$, it is uniformly continuous; hence

$$q(\delta) = \sup_{0 \leq s < t + \delta} |\hat{f}(s) - \hat{f}(t)| \to 0 \text{ as } \delta \to 0.$$

Moreover, $\hat{f}(t)$ is bounded by $1/t$ by Chebychev’s inequality. Hence, equation (7) gives

$$\delta_t(\varepsilon) \leq \min\left(q\left(\frac{t\varepsilon}{c - \varepsilon}\right), \frac{1}{t}\right) + 3 \varepsilon.$$

If $t\varepsilon/(c - \varepsilon) < \sqrt{\varepsilon}$, then $\delta_t(\varepsilon) \leq q(\sqrt{\varepsilon}) + 3 \varepsilon$; while if $t\varepsilon/(c - \varepsilon) \geq \sqrt{\varepsilon}$, then $\delta_t(\varepsilon) \leq 1/t \leq \sqrt{\varepsilon}/(c - \varepsilon) + 3 \varepsilon$.

Remark. Using the same method it is possible to show the counterpart of Theorem 2.1 for the successive return times and the number of visits.
3. Piecewise monotonic transformations

In this section we show that piecewise monotonic maps of Rychlik’s type (even with countably many monotonic pieces) enjoy exponential statistics. Let \( X \subset \mathbb{R} \) be a compact set and \( m \) a Borel regular probability measure on \( X \). The variation of a function \( g : X \to \mathbb{R} \) is defined by

\[
\text{var } g \overset{\text{def}}{=} \sup \left\{ \sum_{j=0}^{k-1} |g(x_{j+1}) - g(x_j)| \right\},
\]

where the supremum is taken along all finite ordered sequences \((x_j)_{j=1}^{k} \) with \( x_j \in X \).

The norm \( \|g\|_{BV} = \sup |g| + \text{var } g \) makes \( BV = \{ g : X \to \mathbb{R} : \|g\|_{BV} < \infty \} \) into a Banach space. We endow \( X \) with the induced topology and denote by \( B(X) \) the Borel \( \sigma \)-algebra of \( X \). We say that \( I \subset X \) is an \( X \)-interval if there exists some interval \( J \subset \mathbb{R} \) such that \( I = X \cap J \).

**Definition 3.1.** (\( \mathcal{R} \)-map) Let \( T : Y \to X \) be a continuous map, \( Y \subset X \) open and dense and \( m(Y) = 1 \). Let \( S = X \setminus Y \). We call \( T \) an \( \mathcal{R} \)-map if the following are true.

1. There exists a countable family \( \mathcal{Z} \) of closed \( X \)-intervals with disjoint interiors (in the topology of \( X \)) such that \( \bigcup_{Z \in \mathcal{Z}} Z \supset Y \) and for any \( Z \in \mathcal{Z} \) the set \( Z \cap S \) consists exactly of the endpoints of \( Z \).
2. For any \( Z \in \mathcal{Z} \), \( T|_{Z \cap Y} \) admits an extension to a homeomorphism from \( Z \) to some \( X \)-interval.
3. There exists a function \( g : X \to [0, \infty) \), with \( \text{var } g < \infty \), \( g|_S = 0 \) such that the operator \( P : L^1(m) \to L^1(m) \) defined by

\[
Pf(x) = \sum_{y \in T^{-1}(x)} g(y) f(y)
\]

preserves \( m \). In other words, \( m(Pf) = m(f) \) for each \( f \in L^1(m) \), that is \( m \) is \( g^{-1} \)-conformal.
4. \( T \) is expanding: \( \sup_{x \in X} g(x) < 1 \).

We first remark that if \( T \) is an \( \mathcal{R} \)-map, then any iterate \( T^n \) is also an \( \mathcal{R} \)-map (see [38, Lemma 2] and the discussion before for details). Given a weight function \( g \) such that \( \sup_X g < 1 \) and \( \text{var } g < \infty \), Liverani et al [25] have shown the existence of a conformal measure \( m \) which fulfills the hypotheses, under the additional assumption that \( T \) is covering: for any interval \( I \subset X \), there exists an integer \( N > 0 \) such that

\[
\inf_{x \in I} P_N^I \chi_I(x) > 0.
\]

**Proposition 3.1.** Suppose that \( X = [0, 1] \) is Lebesgue measure and \( T \) is a piecewise monotonic transformation on \( X \). If:

1. \( T|_{Z \cap X} \) is \( C^2 \) for each \( Z \in \mathcal{Z} \);
2. \( T \) is uniformly hyperbolic, i.e. for some \( M > 0 \), \( \inf |(T^M)'| > 1 \), the infimum being taken on the subset of \( X \) where \( (T^M)' \) is defined;
3. \( T \) has bounded distortion, which means
\[
\sup_{Z \in \mathcal{Z}} \sup_{\mathcal{Z}} \frac{|T''|}{|T'|^2} < \infty \quad \text{and} \quad \sum_{Z \in \mathcal{Z}} \sup_{\mathcal{Z}} \frac{1}{|T'|} < \infty ; \tag{9}
\]
then \( T \) is an \( \mathcal{R} \)-map with weight function \( g = 1/|T'| \) on \( Y \) and \( g = 0 \) on \( S \).

**Proof.** It is enough to check that the variation of \( g = 1/|T'| \) is finite. Since \( g \) is \( C^1 \) on the interior of \( Z \in \mathcal{Z} \), the variation is estimated by
\[
\var g \leq \sum_{Z \in \mathcal{Z}} \int_{Z} |g'(t)| \, dt + 2 \sum_{Z \in \mathcal{Z}} \sup_{\mathcal{Z}} \frac{1}{|T'|} \leq \sup_{Z \in \mathcal{Z}} \sum_{Z} \frac{|T''|}{|T'|^2} + 2 \sum_{Z \in \mathcal{Z}} \sup_{\mathcal{Z}} \frac{1}{|T'|} < \infty . \tag{9}
\]

\( \mathcal{R} \)-maps possess very strong statistical properties, which we collect below.

**Theorem 3.1.** (Rychlik [38]) If \( T \) is an \( \mathcal{R} \)-map, then there exists an invariant measure \( \mu \) which is absolutely continuous with respect to the conformal measure \( m \) with density \( h = d\mu/dm \in BV \). The measures \( m \) and \( \mu \) have no atoms. In addition, there exists a partition (mod \( m \)) of \( X \) into disjoint open sets \( \xi_{i,j} \), where \( i = 1, \ldots, k \) and \( j = 1, \ldots, L_i \) such that each system \( (T^{-L_i}|_{\xi_{i,j}}, \xi_{i,j}, \mu_{\xi_{i,j}}) \) is mixing and has exponential decay of correlations for bounded variation observable, which means that for some \( C \in (0, \infty) \) and \( \theta \in (0, 1) \)
\[
\left| \int \phi \circ T^{nL_i} \psi \, d\mu_{\xi_{i,j}} - \int \phi \, d\mu_{\xi_{i,j}} \int \psi \, d\mu_{\xi_{i,j}} \right| \leq C \|\psi\|_{L^1(m)}(\|\psi\|_{BV})^\theta \tag{10}
\]
for any \( \phi \in L^1(m) \) and \( \psi \in BV \).

This theorem tells us, in particular, that \( X \) can be partitioned (mod \( m \)) into compact sets \( \xi_{i,j} \) where some iterate of \( T \) is again an \( \mathcal{R} \)-map with a mixing measure equivalent to \( m|_{\xi_{i,j}} \) and which has exponential decay of correlations for observable bounded variations.

**Theorem 3.2.** Any \( \mathcal{R} \)-map \( T \) with conformal measure \( m \) and invariant mixing measure \( \mu \ll m \) has exponential return time statistics around balls.

**Proof.** We use the estimate given by [20, Lemma 2.4] to apply [20, Theorem 2.1]. We recall the quantities considered there (\( N \) is any integer).
\[
a_N(U) \overset{\text{def}}{=} \mu_U(\{x : \tau_U(x) \leq N\}),
b_N(U) \overset{\text{def}}{=} \sup_{k \geq 0} [\mu_U(T^{-N}V) - \mu(V) : V \text{ is measurable}],
c(U) \overset{\text{def}}{=} \sup_{k \geq 0} [\mu_U(\{x : \tau_U(x) > k\}) - \mu(\{x : \tau_U(x) > k\})].
\]
We denote by \( h \) the density of the measure \( \mu \) with respect to \( m \). Let \( U \subset X \) be an interval in \( X \) and set \( \tau(U) \overset{\text{def}}{=} \inf\{\tau_U(x) : x \in U\} \). We now compute an upper bound for \( a_N \) and \( b_N \).
Return time statistics via inducing

Obviously \( a_N(U) = \sum_{n=\tau(U)}^N \mu_U(\{x : \tau_U(x) = n\}) \) and for each \( n \geq \tau(U) \)

\[
\mu_U(\{x : \tau_U(x) = n\}) \leq \frac{1}{\mu(U)} \int I_{T^{-n}U} \mu_U \, d\mu \\
= \int \left( \frac{I_{U}}{\mu(U)} \right) \circ T^n \cdot (I_U - \mu(U)) \, d\mu + \mu(U) \\
\leq \frac{C m(U)}{\mu(U)} \|I_U - \mu(U)\|_{BV} \theta^n + \mu(U).
\]

We used for the last inequality the estimate on decay of correlations (10) given by Theorem 3.1, with \( \psi = \frac{1}{\mu(U)} \) and \( \psi = \frac{1}{\mu(U) - \mu(U)} \). Since \( U \) is an interval we have \( \|I_U - \mu(U)\|_{BV} \leq 3 \), hence the summation on \( n = \tau(U), \ldots, N \) gives

\[
a_N(U) \leq 3 \frac{C m(U)}{1 - \theta \mu(U)} \theta^{\tau(U)} + N \mu(U). \tag{11}
\]

We now consider \( b_N(U) \). The decay of correlations given by (10) yields (with \( \psi = \frac{1}{V} \) and \( \psi = \frac{1}{U/\mu(U)} \))

\[
b_N(U) \leq \sup_{V \in B(X)} C \|I_V\|_{L^1(m)} \|I_U\|_{BV} \theta^N / \mu(U) \leq 3 \frac{C \theta^N}{\mu(U)}. \tag{12}
\]

Lemma 2.4 in [20] together with (11) and (12) yield (with \( N = 2 \log \mu(U)/\log \theta \))

\[
c(U) \leq c_1 \frac{m(U)}{\mu(U)} \theta^{\tau(U)} + c_2 \mu(U) + c_3 \mu(U)|\log \mu(U)|, \tag{13}
\]

for some constants \( c_1, c_2 \) and \( c_3 \) independent of the interval \( U \).

Since \( \mu \) has no atoms, the countable union \( W = \bigcup_{j=0}^{\infty} T^{-j}S \) has zero measure. Hence, for \( \mu \)-almost every point \( z \in X \), the iterates \( T^k z \) are well defined and \( T^k z \not\in S \). One easily sees then that \( \tau(U_r(z)) \to +\infty \) as \( r \to 0 \) provided \( z \) is not periodic. Consider the set

\[
G = \left\{ z \in X \mid W : z \text{ is not periodic and } D(z) \overset{df}{=} \lim_{r \to 0} \frac{m(U_r(z))}{\mu(U_r(z))} < +\infty \right\}.
\]

The Lebesgue Density Theorem tells us that \( D(z) \) is \( \mu \)-almost everywhere finite because the density \( h = d\mu/dm > 0 \), \( \mu \)-almost everywhere. Since \( \mu \) is aperiodic (it is ergodic with no atoms), we conclude that \( \mu(G) = 1 \).

Moreover, for all \( z \in G \), using (13) we get \( c(U_r(z)) \to 0 \) as \( r \to 0 \). We conclude then by Theorem 2.1 in [20] that for \( \mu \)-almost all \( z \in X \),

\[
\mu_{U_r(z)} \left( \tau_{U_r(z)} > \frac{t}{\mu(U_r(z))} \right) \to e^{-t}
\]

uniformly in \( t \in [0, \infty) \). \( \square \)

4. Statistics of return times for non-hyperbolic interval maps

Here we prove that a large class of interval maps enjoy exponential statistics for the return time. The strategy is to prove that around almost every point, an interval can be found whose first return map is an \( \mathcal{R} \)-map.
4.1. Smooth maps with critical points. Let $T : [0, 1] \to [0, 1]$ be a $C^2$ interval map. Denote the critical set by $\text{Crit} \overset{\text{def}}{=} \{ x \in [0, 1] : T'(x) = 0 \}$. For this class of systems, the existence of invariant probability measures and their statistical properties have been frequently studied by means of induced maps (jump transformations rather than first return maps) and tower constructions. The situation is best understood for a unimodal map with exponential growth of the derivatives along the orbit of the critical value. This is known as the Collet–Eckmann condition, but a slightly stronger form (involving a slow recurrence condition of the critical point) has been applied by Benedicks and Carleson [3], where the prevalence of such behaviour in the quadratic family is also proven.

Every Collet–Eckmann unimodal map has an absolutely continuous invariant probability measure $\mu$. $\mu$ has exponential decay of correlations (with respect to some iterate of the map) and satisfies the Central Limit Theorem, and the Perron–Frobenius operator with suitable weights has a spectral gap [21, 47]. An important quantity is the tail behaviour of the inducing scheme, i.e. the asymptotic behaviour of $m(\{ x; R(x) > n \})$, where $m$ is the reference measure (Lebesgue) and $R$ the inducing time (playing the role of the first return time in our paper). Collet–Eckmann maps have exponential tail behaviour: $m(\{ x; R(x) > n \}) \leq Ce^{-\alpha n}$ for some $\alpha, C > 0$. In [7], the tail behaviour of induced maps over multimodal maps with arbitrary growth rates on the critical orbits is computed.

The correlation decays were computed using Young’s framework [48].

The multiple return time statistic for Collet–Eckmann maps has been studied (in the Benedicks–Carleson setting) by Boubakri [4]; he found that they have a Poissonian distribution and proved additional fluctuation results. A more general approach is taken by Collet [12], but his result also essentially relies on exponential tail behaviour of the inducing structure.

The theorem below covers certain maps that are not Collet–Eckmann and, therefore (cf. [32]), have a strictly subexponential decay of correlations. One should think of (unimodal) maps with a so-called persistently recurrent critical point, the Fibonacci map being the best known example, see [28]. Such maps frequently admit absolutely continuous invariant probabilities [5, 28], but are never Collet–Eckmann, see [6, Theorem 2]. In this sense, Theorem 4.1 complements Boubakri’s and Collet’s results. The main importance of this theorem is to show that, as long as the measure is mixing, exponential return statistics can be expected, irrespective of the precise rate of mixing; in particular, exponential mixing is not necessary.

We assume that the orbit of the critical set is nowhere dense. This enables us to use a first return map as an induced transformation. The only information on the tail behaviour we need is that $\sum_n m(\{ x; \tau(x) = n \}) < \infty$. This is equivalent to the existence of an invariant probability measure $\mu \ll m$. Furthermore, we state the result for multimodal maps and for $|T'|^t$-conformal measures $m_t$.

**Theorem 4.1.** Let $T : [0, 1] \to [0, 1]$ be as above. Assume that:
1. there exists a non-atomic $|T'|^t$-conformal probability measure $m_t$ for some $t > 0$;
2. $T$ preserves an ergodic probability measure $\mu \ll m_t$; and
3. $m_t(\text{orb(Crit)}) = 0$.
Then $(\text{supp}(\mu), T, \mu)$ has exponential return time statistics.
Remark. A special case is $t = 1$, i.e. $m = m_t$ is Lebesgue measure. A point $c \in \text{Crit}$ is called non-flat if there exists an $\ell$, $1 < \ell < \infty$, such that $|f(x) - f(c)| = \mathcal{O}(|x - c|^{\ell})$. If each critical point is non-flat, then the condition $m(\text{orb(Crit)}) = 0$ follows from

$$\text{orb(Crit)} = \begin{cases} \text{nowhere dense} & \text{if } \# \text{Crit} = 1, \\ \text{a minimal set} & \text{if } 2 \leq \# \text{Crit} < \infty. \end{cases}$$

This was shown by Martens [29] (see also [30, Theorem V.1.3']) if $\# \text{Crit} = 1$ and by Vargas [45] if $2 \leq \# \text{Crit} < \infty$.

The case $t < 1$ comes into view when $T$ has a periodic attractor and the measure $m_t$ is supported on a repelling Cantor set.

**Proof.** Let $X = \text{supp}(\mu) \setminus \text{orb(Crit)}$. Obviously $\mu(X) = 1$. Let $x$ be any recurrent point in $X$; by the Poincaré Recurrence Theorem, this concerns $\mu$-almost every $x \in X$.

Let $Y$ be the component of $[0, 1] \setminus \text{orb(Crit)}$ containing $x$ and $n$ be any integer such that $T^n(x) \in Y$. As orb(Crit) \cap $Y = \emptyset$, there exists a neighborhood $U$ of $x$ such that $T^n$ maps $U$ monotonically onto $Y$. Let $\hat{T}$ be the first return map to $U$. By taking $n$ sufficiently large, we can ensure that $U$ is compactly contained in $Y$ and that $T^i(\partial U) \cap U = \emptyset$ for all $i \geq 0$.

Let $W \subset U$ be any maximal interval on which $T|_W$ is monotone. Since orb($\partial U$) \cap $U = \emptyset$, it follows that $\hat{T} : W \to U$ is onto and, therefore, contains a fixed point, say $p_W$. The derivative $|\hat{T}'(p_W)|$ is uniformly bounded away from 1, see [30, p. 268].

Write $\hat{X} = X \cap U$ and $Z = X \cap W$. Let $Z$ be the partition of $\hat{X}$ into the sets $Z$. We will show that $\hat{T} : \bigcup_{Z \in Z} Z \to \hat{X}$ is an $R$-map.

Given intervals $I \subset J$, $J$ is said to contain a $\delta$-scaled neighborhood of $I$ if both components of $J \setminus I$ have length $\geq \delta|I|$. Let $\delta_0 > 0$ be the distance between $\partial Y$ and $\partial X$.

For each branch $\hat{T}|_W = T^k|_W$ (where $k \overset{\text{def}}{=} \tau_U(W)$ is the return time), there is an interval $W' \supset W$ such that $T^k$ maps $W'$ monotonically onto $Y$. It follows that $T^k(W')$ contains a $\delta_0/|U|$-scaled neighborhood of $T^k(W)$. More precisely, if $x, y \in W$, then $T^k(W')$ contains a $\delta$-scaled neighborhood of $(T^k(x), T^k(y))$. This allows us to use the Koebe Principle.

**Proposition 4.1.** (Koebe Principle) Let $W' \supset W$ be intervals and assume that $T^n : W' \to T(W')$ is a $C^2$ diffeomorphism. If $T^n(W)$ contains a $\delta$-scaled neighborhood of $T^n(W)$, then there exists $K$ such that the distortion

$$\sup_{s,t \in (x,y) \subset W} \frac{\hat{T}'(s)}{\hat{T}'(t)} \leq K. \quad (14)$$

**Remarks.** Historically, the Koebe Principle was proven under the assumption that $T$ has negative Schwarzian derivative, see [30, Chapter III.6]. A recent work of Kozlovski [23], extended to the multimodal case by van Strien and Vargas [42], shows that the $C^2$ assumption suffices. The magnitude of $K = K(\delta) = K_0((1 + \delta)/\delta)^2$, where $K_0$ depends only on the map.
By taking $U$ small, we can choose $K$ as close to 1 as we want. It follows that
$$\inf_{Z \in \mathcal{Z}} \inf_{Z \in \mathcal{Z}} |\hat{T}'(x)| \geq \frac{1}{K} \inf_{Z \in \mathcal{Z}} |\hat{T}'(pw)| > 1,$$
i.e. $\hat{T}$ is expanding.

Since $m_t$ is $g^{-1}$-conformal,
$$m_t(\hat{X}) = \int_{Z} |\hat{T}'(x)|' \, dm_t \leq \sup_{Z} |\hat{T}'(x)|' m_t(Z).$$

By (14),
$$\sup_{Z} g = \sup_{Z} \frac{1}{|\hat{T}'|'} \leq K_0' \inf_{Z} \frac{1}{|\hat{T}'|'} \leq K_0' \frac{m_t(Z)}{m_t(\hat{X})}.$$

This shows that $\sum_{Z} \sup_{Z} g \leq K_0' < \infty$.

Let $I \supset J$ be intervals such that $T|I$ is monotone and let $L$ and $R$ be the components of $I \setminus J$. If $I$ is sufficiently small, $T$ expands the cross ratio if
$$\frac{|T(I)|}{|T(L)|} \geq \frac{|I| |J|}{|L| |R|}.$$  \hspace{1cm} (15)

This is a consequence of the Koebe Principle. It follows that $|\hat{T}'|^{-1/2}$ is convex on each branch and therefore $(d/dx)|\hat{T}'|^{-1/2} = -\frac{1}{2} \hat{T}''|\hat{T}'|^{-3/2}$ is non-decreasing. Hence, each branch domain $(aW, bW) \triangleq W$ contains at most one point $rW$ at which $\hat{T}''$ changes sign. We get
$$\var_{Z} g \leq \var_{W} g$$
$$= \int_{aw}^{rw} |\hat{T}''(s)| \frac{ds}{|\hat{T}'(s)|^{1+t}} + \int_{rw}^{bw} |\hat{T}''(s)| \frac{ds}{|\hat{T}'(s)|^{1+t}}$$
$$\leq \sup_{W} \frac{1}{|\hat{T}'|'} \left[ \log \frac{\hat{T}'(rW)}{\hat{T}'(aw)} + \log \frac{\hat{T}'(bw)}{\hat{T}'(rW)} \right]$$
$$\leq 2K_0' \log K_0 \sup_{Z} g.$$ 

Therefore,
$$\var_{\hat{X}} g \leq \sum_{Z \in \mathcal{Z}} \var_{Z} g + 2 \sum_{Z \in \mathcal{Z}} \sup_{Z} g$$
$$\leq 2(2K_0' \log K_0 + 1) \sup_{Z} g \leq 2K_0'(K_0' \log K_0 + 1) < \infty.$$ 

Thus $\hat{T}$ is a $\mathcal{R}$-map and it satisfies the assumptions of Proposition 3.1. By Theorems 3.2 and 2.1, the conclusion follows because the set of $\hat{X}$ satisfying the above assumptions have full measure. \hfill \Box

In the proof of this theorem we even get that $\mathcal{Z}$ is a Markov partition for the induced map $\hat{T}$ (in fact, each monotone branch is onto). Note that this is much better than what is necessary, since $\mathcal{R}$-maps need not satisfy this extremely strong topological property. This supports our belief that this method could, in principle, be applied to much more general systems, especially those with singularities.
Maps with neutral fixed points. Let \( \alpha \in (0, 1) \) and consider the map \( T_\alpha \) defined on \( X = [0, 1] \) by

\[
T_\alpha(x) = \begin{cases} 
  x(1 + 2^\alpha x^\alpha) & \text{if } x \in [0, 1/2), \\
  2x - 1 & \text{otherwise}.
\end{cases}
\]

Let \( \mu_\alpha \) denote the invariant measure absolutely continuous with respect to Lebesgue (see, e.g., [26] for the existence and properties). The system \((X, T_\alpha, \mu_\alpha)\) has exponential return time statistics around cylinders of some naturally associated partition [20]. Here we prove that this is also true if the neighbourhoods are balls.

**Theorem 4.2.** For any \( \alpha \in (0, 1) \) the system \((X, T_\alpha, \mu_\alpha)\) has an exponential return time statistic.

**Proof.** Let \( \hat{X}_0 = (\frac{1}{2}, 1] \) and for \( n \geq 1 \)

\[
\hat{X}_n = \{ x \in X : T^n(x) > \frac{1}{2} \text{ and for } k = 0, 1, \ldots, n-1, T^k(x) < \frac{1}{2} \}.
\]

Fix \( n \geq 0 \) and let \( \hat{T} : \hat{X} \to \hat{X} \) be the first return map to \( \hat{X} \). We then define a partition of \( \hat{X} \) by \( Z = \{ Z_p : p = 1, 2, \ldots \} \), where \( Z_p = \{ x \in \hat{X} : \hat{T}_k(x) = p \} \).

One can easily check that \( Z \) is a partition into intervals and each branch of \( \hat{T} : Z \to \hat{X} \) is monotone and onto. Let \( m \) be the normalized Lebesgue measure restricted to \( \hat{X} \) and let \( g(x) = \frac{1}{|\hat{T}'(x)|} \) when \( x \in \text{int}(Z) \) for some \( Z \in Z \) and \( g(x) = 0 \) otherwise. In the proof of [26, Proposition 3.3] it is proved that for some constant \( K \),

\[
\sup_{x, y \in Z} \frac{\hat{T}'(x)}{\hat{T}'(y)} \leq K
\]

for all \( Z \in Z \). A straightforward computation shows that

\[
\log K \geq \left| \frac{\hat{T}'(x)}{\hat{T}'(y)} \right| \geq \left| \int_x^y \frac{\hat{T}''(t)}{\hat{T}'(t)} \, dt \right|
\]

for all \( x, y \in Z \) and \( Z \in Z \). Since \( \hat{T} \) is increasing and convex on each \( Z \in Z \), we get

\[
\int_Z \frac{|\hat{T}''(t)|}{|\hat{T}'(t)|^2} \, dt \leq \sup_Z g \log K.
\]

Taking into account that \( \hat{T}Z = \hat{X} \) for any \( Z \in Z \), we get

\[
\sup_Z g \leq K \frac{m(Z)}{m(\hat{T}(Z))} \leq K m(Z).
\]

Therefore, since \( g \) is \( C^1 \) in the interior of \( Z \) and \( g|_{\partial Z} = 0 \),

\[
\text{var } g \leq \sum_{Z \in Z} \int_Z |g'(t)| \, dt + 2 \sum_{Z \in Z} \sup_Z g \leq K (2 + \log K) < \infty.
\]

Finally, it is obvious that \( \sup g < 1 \), hence \( (\hat{X}, \hat{T}, m) \) is an \( \mathcal{R} \)-map. By Theorems 3.2 and 2.1 \( \mu_\alpha \)-almost all points inside \( \hat{X} \) have exponential return time statistics and the conclusion follows since \( \bigcup_{n \geq 0} \hat{X}_n \) has full Lebesgue measure. \( \square \)
5. Complex quadratic maps

In this section we apply the main framework to certain polynomials on the Riemann sphere \( \hat{\mathbb{C}} \). Every rational map \( T \) has a \(|T'|^t\)-conformal measure \( m_t \) for some \( t \in (0, 2] \), see Sullivan [43]. If \( T \) is hyperbolic on the Julia set \( J \), then we can take \( t \) equal to the Hausdorff dimension of \( J \) and \( m_t \) is equivalent to the \( t \)-dimensional Hausdorff measure. In general, however, \( m_t \) can be supported on a proper subset of \( J \); it can even be atomic. This can be an issue if, for example, \( T \) has neutral periodic points.

For our results, we assume that the orbit of the critical point does not densely fill the Julia set, but we do not require a supremum gap as in e.g. [16].

We start with a complex version of an \( R \)-map and show (analogous to Theorem 3.2) that under some additional conditions they have exponential return time statistics.

**Definition 5.1.** (Complex Markov maps) Let \( T : Y \rightarrow X \) be a continuous map, \( Y \subset X \) open subsets of \( \hat{\mathbb{C}} \) and \( m_t(Y) = 1 \), where \( m_t \) is a probability measure and \( 0 < t \leq 2 \).

Let \( S = X \setminus Y \). We call \( T \) a complex Markov map if the following are true.

1. There exists a countable family \( Z \) of pairwise disjoint open discs such that \( \bigcup Z \in Z \)

2. For any \( Z \in Z \), \( T : Z \rightarrow X \) is a conformal diffeomorphism (with \( T(Z) = X \)) and with bounded distortion

\[
\sup_{Z \in Z} \sup_{Z} \frac{|T''|}{|T'|^2} < \infty. \tag{16}
\]

3. The measure \( m_t \) is \(|T'|^t\)-conformal.

4. The map \( T \) is expanding: \( \inf_{y \in Y} |T'(y)| > 1 \).

5. Let \( Z_k = Z \vee T^{-1}Z \vee \cdots \vee T^{-(k-1)}Z \) be the \( k \)th join of the partition \( Z \). The domains \( Z \in Z_k \) are uniformly convex-like, by which we mean

\[
\sup_{k} \sup_{Z \in Z_k} \sup_{x \neq y \in Z} \frac{p_Z(x, y)}{|x - y|} < \infty, \tag{17}
\]

where \( p_Z(x, y) \) denotes infimum of the lengths of the path in \( Z \) connecting \( x \) and \( y \).

Analogous to Theorem 3.1 one can show that complex Markov maps have an invariant measure with an exponential decay of correlations.

**Theorem 5.1.** Let \( T \) be a complex Markov map as above. There exists an invariant ergodic probability measure \( \mu \) equivalent to \( m_t \). Moreover \( (X, T, \mu) \) is mixing with exponential decay of correlations. There exists \( C > 0 \) and \( \rho \in (0, 1) \) such that for any \( f \) Lipschitz and \( g \in L^1_\mu \)

\[
\left| \int f \cdot g \circ T^n d\mu - \int f d\mu \int g d\mu \right| \leq C \|f\|_{\text{Lips}} \|g\|_{L^1_\mu} \rho^n, \tag{18}
\]

where

\[
\|f\|_{\text{Lips}} = \sup |f| + \sup_{x \neq y} \frac{|f(x) - f(y)|}{|x - y|}.
\]
Proof. First let us make the following remark. As $T$ is expanding, a straightforward calculation shows that (16) implies

$$K := \sup_{n \in \mathbb{N}} \sup_{Z_n} \sup_{w \in Z} \frac{|(T^n)^y|}{|(T^n)^y|^2} < \infty$$

and $\sum_{Z_n \in Z_n} |(T^n)|^{-t} < \infty$ uniformly in $n$. Let $P_n$ be the Perron–Frobenius operator

$$\langle P_n f \rangle (z) = \sum_{T(y) = z} \frac{f(y)}{|T(y)|^t}.$$

Let us write $\|f\|_s$ for the seminorm $\sup_{z \neq z'} |f(z) - f(z')|/|z - z'|$. If $\|f\|_{\text{Lips}} < \infty$, we have

$$\|P_n f\|_s \leq \sup_{z, z' \in \mathcal{Y}} \frac{1}{|z - z'|} |P_n f(z) - P_n f(z')| \leq \sup_{z, z' \in \mathcal{Y}} \frac{1}{|z - z'|} \left\{ \sum_y \frac{|f(y) - f(y')|}{|(T^n)^y(y)|^t} + \sum_y \frac{|f(y')|}{|(T^n)^y(y)|^t} - \frac{1}{|(T^n)^y(y')|^t} \right\}.$$

Here we have summed over the pairs $y, y'$ in the same atom $Z_n \in Z_n$ with $T^n(y) = z$ and $T^n(y') = z'$. As $T : \mathcal{Y} \to X$ is onto for every $Z \in Z$, these pairs are well defined. The first term in the above expression is bounded by

$$\sum_{Z_n} \sup_{y, y' \in Z_n} \frac{|f(y) - f(y')|}{|y - y'|} \frac{1}{|(T^n)^y(y)|^t} \|P_n \|_{\infty} \sup_{y \in \mathcal{Y}} \frac{1}{|(T^n)^y(y')|^t} \leq \|f\|_{s} \|P_n \|_{\infty} \sup_{y \in \mathcal{Y}} \frac{1}{|(T^n)^y(y')|^t}.$$

Next we use the Mean Value Theorem and (17) to estimate

$$\left| \frac{1}{|(T^n)^y(y')|^t} - \frac{1}{|(T^n)^y(y')|^t} \right| \leq \tilde{K} \left( \frac{1}{|(T^n)^y(w)|^t} \right) |y - y'|$$

$$= \tilde{K} |||y - y'| \left( (T^n)^y(w) \right) |^t| (T^n)^y(w) |^t - 1 |(T^n)^y(w) |^2,$$

for some $w$. The constant $\tilde{K}$ is an upper bound in (17). This gives, for the second term,

$$\sup_{Z \in Z} \sup_{z, z' \in Z} \sum_{y} \frac{f(y')}{|z - z'|} \left| \frac{1}{|(T^n)^y(y')|^t} - \frac{1}{|(T^n)^y(y')|^t} \right|$$

$$\leq \|f\|_{s} \sum_{y, y' \in Z_n} \frac{1}{|(T^n)^y(y')|^t} \left| \frac{1}{|(T^n)^y(y')|^t} - \frac{1}{|(T^n)^y(y')|^t} \right|$$

$$\leq \|f\|_{s} \sum_{y, y' \in Z_n} \frac{\tilde{K} |y - y'| |(T^n)^y(w)|}{|(T^n)^y(w)|^t |(T^n)^y(w)|^t - 1 |(T^n)^y(w)|^2}$$

$$\leq 2 \tilde{K} \|f\|_{s} \|P_n \|_{\infty}.$$

Let $\theta = \sup |T|^t - 1 \in (0, 1)$. Then

$$\frac{\|P_n f\|_{s}}{\|P_n \|_{\infty}} \leq \theta^n \|f\|_{s} + 2 \tilde{K} \|f\|_{s}. $$
Obviously, \( \|P^n_t f\|_{\infty} \leq \|f\|_{\infty} \|P^n\|_{\infty} \). Therefore,

\[
\frac{\|P^n_t f\|_{\text{Lips}}}{\|P^n\|_{\infty}} \leq \theta^n \|f\|_{\text{Lips}} + (2K\tilde{K} + 1)\|f\|_{\infty}.
\]

By construction,

\[
\|P^n_t\|_{\infty} = \sum_{Z \in Z} \sup_{Z} \frac{1}{|(T^n)^y|} < \infty
\]

uniformly in \(n\). This allows us to use the Tulcea–Ionescu and Marinescu Theorem, which shows that \(P_t\) is a quasicompact operator. Since each branch is onto, \(1\) is a simple eigenvalue with Lipschitz eigenvector \(h > 0\) and is the unique eigenvalue on the unit circle. Consequently, for any Lipschitz function \(f\) we have

\[
\left\| P^n_t (fh) - h \int f \, d\mu \right\|_{\text{Lips}} \leq C_0 \|fh\|_{\text{Lips}} \rho^n,
\]

for some \(C_0 > 0\) and \(\rho \in (0,1)\). It follows that the correlations between Lipschitz functions \(f\) and \(L^1_{\mu}\) functions decays exponentially fast: if \(g \in L^1_{\mu}\) we find

\[
\left| \int f \cdot g \circ T^n \, d\mu - \int f \, d\mu \int g \, d\mu \right| = \left| \int \left( P^n_t (fh) - h \int f \, d\mu \right) g \, dm_t \right| \\
\leq \left\| P^n_t (fh) - h \int f \, d\mu \right\|_{\infty} \int |g| \, dm_t \\
\leq C \|f\|_{\text{Lips}} \|g\|_{L^1_{\mu}} \rho^n,
\]

for \(C = C_0 \|h\|_{\text{Lips}} \|1/h\|_{\infty} \). \(\square\)

**Theorem 5.2.** Any complex Markov map \(T\) as defined above, with \(|T'|^t\)-conformal measure \(m_t\), for some \(t > 1\), admits an invariant mixing measure \(\mu\) equivalent to \(m_t\) with exponential return time statistics around balls.

The proof of Theorem 5.2 is similar to that of Theorem 3.2. The additional difficulty is that the decay of correlation is given for the Lipschitz function and not the characteristic function of balls. The usual way to overcome this problem is to approximate balls by a union of small cylinders. This is the object of the next lemmas. Note that if we restrict ourselves to cylinder sets, then the theorem is valid for all \(t > 0\).

As before, let \(Z_k = Z \lor T^{-1}Z \lor \cdots \lor T^{-k+1}Z\) denote the \(k\)-dynamical partition and \(B_k\) the \(\sigma\)-algebra generated by \(Z_k\).

**Lemma 5.1.** Let \(T\) be a complex Markov map. There exist some constants \(\Gamma\) and \(\gamma > 0\) such that for any set \(A \in B_k\) and Borel set \(B\) we have

\[
|\mu(A \cap T^{-n-k}B) - \mu(A)\mu(B)| \leq \Gamma \mu(A)\mu(B) \exp(-\gamma n).
\]

**Proof.** We can rewrite (19) as

\[
\left| \int h^{-1} \cdot P^k_t \cdot (h\mathbb{1}_A) \cdot \mathbb{1}_B \circ T^n \, d\mu - \mu(A)\mu(B) \right| \leq \Gamma \mu(A)\mu(B) \exp(-\gamma n).
\]
where \( h = d\mu/dm_t \) is Lipschitz and bounded away from below (see \([46]\)) and \( P_t \) is the Perron–Frobenius operator as defined in the previous proof. Recall also that

\[
K \overset{\text{def}}{=} \sup_{k \in \mathbb{N}} \sup_{Z \in \mathcal{Z}_k} \sup_Z \frac{|(T^k)'|}{|(T^k)'|^2} < \infty.
\]

Since \( T^k : A \to X \) is one-to-one and onto when \( A \in \mathcal{Z}_k \), the above facts imply that

\[
\sup_{k \in \mathbb{N}} \sup_{A \in \mathcal{Z}_k} \frac{\|h - 1\|_{Lips} \mu(A)}{\mu(A)} < \infty.
\]

The lemma now follows from (18) in Theorem 5.1 by taking \( f = P_t^k(1_A)/\mu(A) \) and \( g = \mu(A)1_A \).

**LEMMA 5.2.** There exists \( \alpha > 0 \) such that for any \( z \in Y \), \( r > 0 \) and \( k > 0 \) we have

\[
\mu(\mathcal{B}_k(U_r(z)) \cap \mathcal{B}_k(U_r(z)^c)) \leq \exp(-\alpha k),
\]

where \( U_r(z) \) denotes the ball of radius \( r \) about the point \( z \).

**Proof.** Let us assume for simplicity that \( \text{diam}(Y) \leq 1 \). We denote by \( \text{int}_JS \) the interior of a subset \( S \subset J \) in the induced topology. Since \( T \) is expanding, there exists \( a \in (0, 1) \) such that \( \text{diam}(Z) < a^k \) for any \( Z \in \mathcal{Z}_k \) and integer \( k \). By the Markov property, the bounded distortion and the conformality of the map \( T \), we can find some constant \( c > 0 \) such that the following property holds. For any integer \( k \) and cylinder \( Z \in \mathcal{Z}_k \) there exists \( p_Z \in \text{int}_JZ \) and \( r_Z > c \text{diam}(Z) \) such that \( U_rZ(p_Z) \cap \text{int}_JZ = \emptyset \) for any \( Z \neq Z' \in \mathcal{Z}_k \) different from \( Z \). Given \( Z \neq Z' \in \mathcal{Z}_k \), we have \( d(p_Z, p_{Z'}) > \max(r_Z, r_{Z'}) \); in particular, \( U_{r_Z/2}(p_Z) \cap U_{r_{Z}/2}(p_{Z'}) = \emptyset \).

Let \( x \in Y, r > 0 \) and consider the following partition

\[
\mathcal{P} = \{ Z \in \mathcal{Z}_k : Z \subset \mathcal{B}_k(U_r(z)) \}.
\]

Let \( \mathcal{P}_n = \{ Z \in \mathcal{P} : a^n < \text{diam}(Z) \leq a^{n-1} \} \). Any \( Z \in \mathcal{P}_n \) is a subset of the annulus \( S_n(z, r) \overset{\text{def}}{=} U_{r+a^n}(z) \setminus U_{r-a^n}(z) \). Thus there exist \( \text{card} (\mathcal{P}_n) \) disjoint balls of radius at least \( a^n/2 \) inside \( S_n(z, r) \). Since the area of \( S_n(z, r) \) is equal to \( 4\pi r a^n \) when \( a^n \leq r \), we get

\[
\text{card} (\mathcal{P}_n) \leq \frac{4\pi r a^n}{c^2 a^{2n}/4} = \frac{8\pi}{c^2} r a^{-n} \leq \frac{8\pi}{c^2} a^{-n}.
\]

Obviously when \( a^n > r \) we also have

\[
\text{card} (\mathcal{P}_n) \leq \frac{8\pi}{c^2} \leq \frac{8\pi}{c^2} a^{-n}.
\]

Since the measure \( m_t \) is \( |T'|^t \)-conformal and the map itself is conformal and Markov, we have for some constant \( c_1, m_t(Z) < c_1 \text{diam}(Z)^t \) for any \( Z \in \mathcal{Z}_k \) for some \( k \). The previous
inequalities imply (observe that $P_n = \emptyset$ if $n \leq k$ and recall that $t > 1$)

$$
\mu\left( \bigcup_{Z \in P} Z \right) = \sum_{n > k} \mu\left( \bigcup_{Z \in P} Z \right) \\
\leq \sum_{n > k} \max\{\mu(Z) : Z \in P_n\} \text{card}(P_n) \\
\leq \sum_{n > k} c_1 a^{-1} a^n \frac{8\pi}{c_2} a^{-n} \\
= \frac{8\pi c_1}{(a - a')c_2} a^{(t-1)k}.
$$

Taking $\alpha \in (0, (1 - t) \log a)$ sufficiently small gives the result. \hfill \square

**Proof of Theorem 5.2.** The proof closely follows from that of Theorem 3.2; we use the same notation $a_N$ and $b_N$. Let $U = U_r(z)$ and $k, N \in \mathbb{N}$ be chosen later. By Lemmas 5.1 and 5.2

$$
a_N(U) \leq \sum_{n = \tau(U)}^N \frac{1}{\mu(U)} \mu(B_n(U) \cap T^{-n}U) \\
\leq (1 + \Gamma) \sum_{n = \tau(U)}^N \mu(B_n(U)) \\
\leq \frac{1 + \Gamma}{1 - \exp(-\alpha)} [N \mu(U) + \exp(-\alpha \tau(U))].
$$

Similarly, we get by Lemmas 5.1 and (twice) Lemma 5.2

$$
b_N(U) \leq \Gamma \mu(B_k(U)) \exp[-\gamma(N - k)] + \frac{1}{\mu(U)} \mu(B_k(U) \cap B_k(U^c)) \\
\leq \Gamma \exp[-\gamma(N - k)] + \frac{1}{\mu(U)} (\Gamma \exp[-\alpha k - \gamma(N - k)] + \exp[-\alpha k]),
$$

for all $k \leq N$. Taking $k = -(2/\alpha) \log \mu(U)$ and $N = 2k$ gives

$$
b_N(U) \leq \Gamma \mu(U)^{2/\alpha} + \Gamma \mu(U)^{1+2/\alpha} + \mu(U).
$$

For all non-periodic points $z \notin \bigcup_{k \in \mathbb{N}} \partial Z_k$ we have $\tau(U_r(z)) \to \infty$, which implies $c(U_r(z)) \to 0$ as $r \to 0$. Since this concerns $\mu$-almost all points in $J$, the theorem is proved. \hfill \square

We will apply these results to quadratic maps on $\mathbb{C}$. Induced systems have been used before for rational maps, notably by Aaronson et al [1]. They consider parabolic rational maps (i.e. rational maps whose Julia sets contain no critical point but rationally indifferent periodic points) and establish the existence of an invariant measure $\mu \ll m_t$, where $m_t$ is a $t$-conformal measure with $t = \text{HD}(J)$. Moreover, $\mu$ is finite if and only if

$$
t \min_p \frac{a(p) + 1}{a(p)} > 2.
$$
Here, the minimum is taken over all parabolic points \( p \) and \( a(p) \) is such that \( T^q(z) = z + a(z - p)^{n(p)} + \cdots \) for the appropriate iterate \( q \). It follows that \( \mu \) is finite only if \( t > 1 \), which is the hypothesis in Theorem 5.2. It is to be expected, therefore, that parabolic rational maps with a finite invariant measure \( \mu \ll m_t \) have exponential return time statistics on balls.

**Theorem 5.3.** Let \( T(z) = z^2 + c \) be a quadratic map on \( \mathbb{C} \) such that \( T \) is not infinitely renormalizable (see the discussion below) and its Julia set \( J \) contains no Cremer points. Suppose also that for some \( t > 1 \):

- \( J \) supports a non-atomic \( |T'| \)-conformal measure \( m_t; \)
- \( m_t(\text{orb(Crit)}) = 0; \) and
- \( T \) preserves a probability measure \( \mu \) equivalent to \( m_t \).

Then \( (\text{supp}(\mu), T, \mu) \) has exponential return time statistics on disks.

The Hausdorff dimension of the Julia set \( \text{HD}(J) > 1 \) for each parameter \( c \) in the Mandelbrot set \( \mathcal{M} \) (see Zdunik [51]); the two exceptions \( c = 2 \) and \( c = 0 \) are easy real one-dimensional cases. So assuming that these parameter values allow a \( t \)-conformal measure with \( t = \text{HD}(J) \), the condition \( t > 1 \) is no restriction. By continuity, there are many parameters close to \( \mathcal{M} \) that give \( t > 1 \) as well.

Note that we allow \( T \) to have parabolic points or Siegel disks. The map \( T \) is called renormalizable if there exist open disks \( W_0 \) and \( W_1 \), \( 0 \in W_0 \subset W_1 \), such that \( T^n : W_0 \to W_1 \) is a two-fold covering map for some \( n \geq 2 \) and \( T^n(0) \in W_1 \) for all \( i \geq 1 \). If there are infinitely many integers \( n \) such that this is possible, \( T \) is infinitely renormalizable. We assume that \( T \) is not infinitely renormalizable and has no Cremer point to be able to use Yoccoz’s puzzle construction. In particular, the result that for each \( z \in J \), the puzzle pieces \( P_n(z) \) containing \( z \) shrink to \( z \) as \( n \to \infty \) is important.

For an exposition of Yoccoz’s puzzles and the proof of these statements, we refer the reader to [31].

Yoccoz’s results have been extended to certain infinitely renormalizable polynomials by Lyubich [27] and Levin and van Strien, [24]. For reasons of simplicity, we have not tried to extend Theorem 5.3 to these cases; we prefer to work with a single set of initial puzzle pieces \( P_0 \). Prado [37] has shown that in all of the above cases, the conformal measure \( m_t \) is ergodic.

**Proof.** Let \( z \in \text{supp}(\mu) \setminus \text{orb(Crit)} \) be arbitrary and let \( U \supset V \ni z \) be open disks such that \( U \cap \text{orb(Crit)} = \emptyset \) and \( V \) is compactly contained in \( U \). Let \( \log \delta = (\text{mod } U \setminus V) > 0 \) be the modulus of \( U \setminus V \). Assume also that \( V \) is convex-like in the sense that \( \sup_{x \neq y \in V} \frac{p_V(x, y)}{|x - y|} < \infty \), where \( p_V \) is as in (17).

The strategy is to find a subset \( \hat{X} \) of \( V \) such that \( T^n(\partial \hat{X}) \cap \hat{X} = \emptyset \) for all \( n \geq 0 \) and then we can invoke Theorem 5.2.

If \( J \) is a Cantor set, we can assume that \( \partial V \) is contained in the Fatou set \( F \), which is the basin of \( \infty \) in this case. Moreover, there are no neutral or stable periodic orbits. Thus each point in \( F \), in particular \( \partial V \), converges to \( \infty \). It follows that \( T^n(\partial V) \) intersects \( V \) for at most finitely many \( n \geq 0 \). Let \( \hat{X} \) be the component of \( V \setminus \bigcup_{n \geq 0} T^n(\partial V) \) containing \( z \). Then \( T^n(\partial \hat{X}) \cap \hat{X} = \emptyset \) for all \( n \geq 0 \) as required. Since \( \hat{X} \) consists
of the intersection and difference of at most finitely many, convex-like disks, we find $\sup_{x \neq y \in \hat{X}} p_{\hat{X}}(x, y)/|x - y| \leq C(\hat{X}) < \infty$.

Assume now that $J$ is connected and, by Yoccoz’s results, also locally connected. Let $F_i, i \geq 0$, be the periodic components of the Fatou set, with $F_0$ the basin of $\infty$. Since $T$ is a polynomial (with exceptional point $\infty$), $J = \partial F_0$. There are only finitely many such components and by Sullivan’s Theorem (see e.g. [44]), every $z' \in F$ is eventually mapped into $\bigcup_i F_i$. We construct a special forward invariant subset $G$ of $\bigcup_i F_i$.

1. Consider the renormalization $T^n : W_0 \to W_1$ of the highest possible period $n$. (If $T$ is not renormalizable, then we just take $T : \mathbb{C} \to \mathbb{C}$.) It is known that $W_1$ contains an $n$-periodic point $p$ with at least two external rays, say $A_0$ and $A'_0$. The existence of such external rays (and the arcs $A_i$ defined later on is guaranteed by results initiated by Douady, see [35] and references therein). Let $G_0 = \{z \in \mathbb{C}; |z| > 1\}$.

2. If $F_i, i \geq 1$, contains a stable periodic point, let $G_i$ be a disk compactly contained in $F_i$ such that $T^{per(F_i)}(G_i) \subset G_i$ and orb(Crit $\cap F_i) \subset G_i$. There is at least one $per(F_i)$-periodic point $p_i$ in the boundary of $F_i$. Let $A_i$ be a smooth compact arc connecting $p_i$ and $G_i$ such that $T^{per(F_i)}(A_i) \subset A_i \cup G_i$. Since $p_i \in \partial F_0$, there is also an external ray $A'_i$ landing at $p_i$.

3. If $F_i$ contains a parabolic point $p_i$ in its boundary such that each $z \in F_i$ converges to $p_i$, let $G_i \subset F_i$ be a disk such that $T^{per(F_i)}(G_i) \subset G_i$, orb(Crit $\cap F_i) \subset G_i$ and $\partial G_i \cap \partial F_i = \{p_i\}$. Let $A'_i \subset F_0$ be an external ray landing at $p_i$.

Let

$$G = \bigcup_{i \geq 0} \{G_i \cup \{p_i\} \cup A_i \cup A'_i\}.$$

Then $G$ is connected and for some $N \in \mathbb{N}$, $\bigcup_{j=1}^N T^j G$ is forward invariant. We start a Yoccoz puzzle construction by putting, for $n \geq 0$,

$$P_n = \{\text{components of } \hat{C} \setminus T^{-n} G\}.$$

For each $n \geq 1$, $T$ maps any element of $P_n$ into an element of $P_{n-1}$. Using the arguments in [31], one can show that the diameters of the elements $Y \in P_i$ tend to 0 as $i \to \infty$, unless $Y$ eventually intersects a Siegel disk.

We can assume that the point $z \notin \bigcup_n T^{-n}(G)$. Moreover, since orb(Crit) densely fills the boundary of any Siegel disk and $m_1(\text{orb(Crit)}) = 0$, we can assume that $z$ does not lie on the boundary of a Siegel disk. Find $n$ so large that the element $Y$ of $P_n$ containing $z$ is contained in $V$. Let $\hat{X} = V \cap Y$. Then $T^n(\partial \hat{X}) \cap \hat{X} = \emptyset$ for all $n \geq 0$. Note also that $T^n(Y)$ is bounded by finitely many smooth curves of $\partial G_i, A_i$ and $A'_i$. At worst these curves end in a logarithmic spiral, namely as they approach the hyperbolic periodic points $p_i$. Therefore, $T^n(\hat{X})$ is also convex-like and obviously simply connected. It follows that $\sup_{x \neq y \in \hat{X}} p_{\hat{X}}(x, y)/|x - y| \leq C(\hat{X}) < \infty$.

The rest of the argument works for both $J$ locally connected and $J$ a Cantor set. Let $\tilde{T} : \hat{X} \to \hat{X}$ be the first return map to $\hat{X}$. Then $\tilde{T}$ is defined on a countable collection $\mathcal{Z}$ of disks $\mathcal{Z}$. The modulus mod$(U \setminus \hat{X}) \geq \log \delta$ and for each branch $\tilde{T} = T^r : \mathcal{Z} \to \hat{X}$ there exists a disk $Z' \supset Z$ such that $T^r$ maps $Z'$ univalently onto $U$. It follows from the
Koebe $\frac{1}{4}$-Theorem (e.g. [8, Theorem 1.4]) that the distortion of $\hat{T}|_Z$ is uniformly bounded:

$$\sup_{x, y \in Z} \frac{|\hat{T}'(x)|}{|\hat{T}'(y)|} \leq K = K(\delta).$$

(21)

More precisely, take $x \in Z$ and let $[x, y] \subset Z$ be a straight arc containing $x$ such that $\hat{T}''/\hat{T}'$ varies little on $A$. Then

$$\frac{|\hat{T}''(x)|}{|\hat{T}'(x)|} \leq \frac{2}{|y - x|} \left| \int_x^y \frac{\hat{T}''(u)}{\hat{T}'(u)} \, du \right| \leq \frac{2}{|y - x|} \log \frac{|\hat{T}'(y)|}{|\hat{T}'(x)|}.$$

To estimate this, let $B$ be the maximal round disk centred at $x$ contained in $Z'$. Let $\delta_0$ be the radius of $B$; we have $\delta_0 |\hat{T}'(x)| = O(\delta)$. Define

$$f(w) = \frac{\hat{T}(x + \delta_0 w) - \hat{T}(x)}{\delta_0 \hat{T}'(x)}.$$

Then $f$ is a univalent map on the unit disk with $f'(0) = 1$. By [8, Theorem 1.6], we obtain

$$\frac{|\hat{T}''(x)|}{|\hat{T}'(x)|^2} \leq \frac{1}{|\hat{T}'(x)|} \log \frac{|f'(y - x) / \delta_0|}{|f'(0)|} \leq \frac{1}{|\hat{T}'(x)|} \left[ \log \left( 1 + \frac{|y - x|}{\delta_0} \right) - 3 \log \left( 1 - \frac{|y - x|}{\delta_0} \right) \right] \leq \frac{5|y - x|}{\delta_0 |\hat{T}'(x)|},$$

provided $y$ is close to $x$. Therefore,

$$\frac{10}{\delta_0 |\hat{T}'(x)|},$$

proving that

$$\sup_{x, y \in Z} \sup_{Z \in Z} \frac{|\hat{T}''(x)|}{|\hat{T}'(x)|^2} < \infty.$$

(22)

The distortion bound $K(\delta)$ also applies by the same argument to iterates $\hat{T}^n$ of the induced map. Therefore, each domain $Z \in Z_n$ is not much less convex than $\hat{X}$:

$$\sup_{x, y \in Z} \sup_{Z \in Z} \frac{p_Z(x, y)}{|x - y|} \leq C$$

for some $C = C(\delta, \hat{X}) < \infty$.

We can also assume that $V$ and hence $\hat{X}$ is so small that $\inf_{x \in Z} |\hat{T}'(x)| > 1$. Thus $\hat{T}$ is hyperbolic. Recall that $m_t$ is the $|T'|$-conformal measure of $T$. As $\hat{T}$ is a first return map, it is straightforward to show that $\hat{m}_t = m_t / m_t(\hat{X})$ is a $|\hat{T}'|$-conformal map for $\hat{T}$. In fact, $\hat{m}_t$ can also be constructed using Sullivan’s techniques [43]. Now we can invoke Theorem 5.2 with the invariant measure $\mu = (1/\mu(\hat{X}))\mu$. $\square$
