We report on the observation of linear and circular magnetogyrotropic photogalvanic effects in InSb/AlInSb quantum well structures. We show that intraband (Drude-like) absorption of terahertz radiation in the heterostructures causes a *dc* electric current in the presence of an in-plane magnetic field. The photocurrent behavior upon variation of the magnetic field strength, temperature and wavelength is studied. We show that at moderate magnetic fields the photocurrent exhibits a typical linear field dependence. At high magnetic fields, however, it becomes nonlinear and inverses its sign. The experimental results are analyzed in terms of the microscopic models based on asymmetric relaxation of carriers in the momentum space. We demonstrate that the observed nonlinearity of the photocurrent is caused by the large Zeeman spin splitting in InSb/AlInSb structures and an interplay of the spin-related and spin-independent roots of the magnetogyrotropic photogalvanic effect.

I. INTRODUCTION

Indium antimonide based quantum wells (QWs) have attracted growing attention for high-speed transistors[1], quantum computing[2,3] and infrared lasers[4]. This novel material is the subject of numerous experimental studies of transport, optical, magneto-optical and spin-related phenomena[1–14]. The characteristics driving the interest in this novel narrow gap material are the high carrier mobility, small effective masses, large Landé g^*-factor, possibility of the mesoscopic spin-dependent ballistic transport and a strong spin-orbit coupling. The latter gives rise to a number of optoelectronic effects such as, e.g., terahertz photoconductivity[15] and the circular photogalvanic effect[16–22] recently observed in InSb QWs[23]. Investigation of photogalvanic effects in the presence of a magnetic field should provide further access to nonequilibrium processes in low-dimensional structures yielding information of such details as the anisotropy of the band spin-splitting, processes of momentum and energy relaxation, symmetry properties and the Zeeman spin splitting, for review see[16,24,25].

Here we report on the observation and detailed study of the magneto-gyrotropic photogalvanic effects (MPGE)[25,26] in *n*-doped InSb/AlInSb QWs induced by terahertz (THz) radiation. We discuss both the linear magnetogyrotropic photogalvanic effect (LMPGE), which can be induced by linearly polarized or unpolarized radiation, as well as the circular magnetogyrotropic photogalvanic effect (CMPGE), which results in the light helicity dependent photocurrent and reverses its direction upon switching the sign of the circular polarization. We show that in InSb/AlInSb QWs the narrow energy gap and the strong spin-orbit coupling combined with

the large Landé g^*-factor result in a photocurrent orders of magnitude larger than that reported for GaAs- and InAs-based QWs, for review see[25]. Moreover, in contrast to previous studies, the observed photocurrent exhibits a peculiar magnetic field dependence: while for moderate magnetic fields (< 1 T) the LMPGE current has a typical linear dependence on magnetic field $\boldsymbol{B}$, at higher magnetic fields it becomes nonlinear and reverses its sign. By contrast, the CMPGE remains linear in the whole range of investigated magnetic fields. The experimental results are analyzed in terms of spin[27–29] and orbital[29–31] microscopic models of the magneto-gyrotropic photogalvanic effect based on the asymmetry of the relaxation of carriers in the momentum space. We demonstrate that specific magnetic field dependences observed for the LMPGE are due to the nonlinear Zeeman spin-splitting in InSb/AlInSb QWs which is enhanced by the electron-electron exchange interaction and causes a nonlinear increase of the spin-related MPGE.

II. SAMPLES AND EXPERIMENTAL TECHNIQUES

We investigated two *n*-type InSb/AlInSb single quantum well structures grown by molecular beam epitaxy onto semi-insulating nominally (001)-oriented GaAs substrate. A QW of width, L_W, is confined on each side by an InAlSb barrier, with a Te modulation doped layer 20 nm above the QW (ME1833 and ME2507 with $L_W = 20$ nm and 30 nm, respectively)[10,13]. The calculated conduction band profile, electron wave function and doping position of the 20 nm QW are shown in Fig. 1(a). The data are obtained by a self-consistent

solution of the Schrödinger and Poisson equations[13]. The QW with $L_W = 20$ nm (30 nm) width contains a two dimensional electron gas with the carrier density of $N_s \approx 3 \times 10^{11}$ cm^{-2} (5×10^{11} cm^{-2}) and the mobility of $\mu_e \approx 5 \times 10^4$ cm^2/ V·s (15×10^4 cm^2/ V·s) for T below 77 K. The temperature dependence of μ_e and N_s measured in the 20 nm QW structure by low-field Hall effect are shown in Fig. 1(b). The samples have square shape and two pairs of ohmic contacts on opposite side of the edges (see inset in Fig. 2) oriented along $x \parallel [1\bar{1}0]$ and $y \parallel [110]$. The photocurrents have been investigated in the temperature range of $T = 4.2$ to 270 K using an optical cryostat with a superconducting magnet. The external magnetic field $\boldsymbol{B}$ up to ± 7 T has been applied parallel to the interface plane along x-direction.

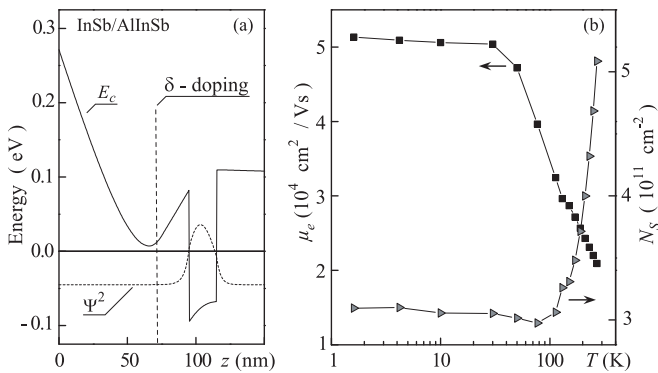

FIG. 1: a) Conduction band profile and electron wavefunction of QW structure with $L_W = 20$ nm calculated within a self consistent Schrödinger-Poisson model[13]. b) Temperature dependences of mobility μ_e and carrier density N_s obtained by the low-field Hall measurements in 20 nm QW sample.

To generate photogalvanic currents we applied a continuous-wave (cw) and pulsed molecular lasers optically pumped by CO_2 lasers. For low power cw radiation we used a CH_3OH laser operating at wavelength $\lambda = 118\,\mu$m (frequency $f = 2.5$ THz) with a power $P \approx 2$ mW at the sample position. The radiation was modulated at 120 Hz, allowing the detection of the photoresponse by the standard lock-in technique. High power radiation is obtained by a pulsed NH_3 laser optically pumped by a transversely excited atmosphere TEA-CO_2 laser and operating at wavelengths $\lambda = 90.5$, 148 or $280\,\mu$m (frequencies $f = 3.3$, 2 and 1.1 THz, respectively). More details on the system can be found in[32–36]. Here, we used single pulses with a duration of about 100 ns, peak power of $P \approx 5$ kW, and a repetition rate of 1 Hz. The photocurrents in unbiased structures are measured via the voltage drop across a 50 Ω load resistor with a storage oscilloscope. The radiation power of cw and pulsed radiation has been controlled by a pyroelectric detector, calorimeter and THz photon drag detector[37], respectively. A typical spot diameter is from 1 to 3 mm. The beam has an almost Gaussian form, which is measured by a pyroelectric camera[38].

All experiments are performed at normal incidence of light. Photocurrents are measured perpendicularly (J_y) and parallel (J_x) to the applied magnetic field (B_x), referred to as tranverse and longitudinal photocurrents, respectively. Our lasers emit linearly polarized radiation with the electric field vector of the THz radiation oriented along the y-axis. In order to rotate the electric field vector $\boldsymbol{E}$ by the angle α ($\alpha = 0°$, $\boldsymbol{E} \parallel y$) we used a $\lambda/2$ plate. To excite the circular photocurrent we changed the radiation helicity, P_{circ}, by rotating the $\lambda/4$ plate by the angle φ between the initial linear polarization of the laser light and the plate optical axis. In this way, the helicity of the incident light can be varied from -1 (left-handed circular, σ_-) to $+1$ (right-handed circular, σ_+) according to $P_{circ} = \sin 2\varphi$.

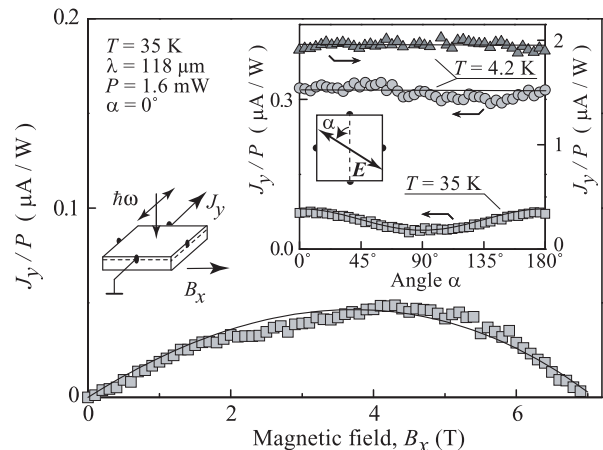

FIG. 2: Magnetic field dependence of J_y/P for $\lambda = 118\,\mu$m and $T = 35$ K. Lines are fit after Eq. (15). The left inset shows the experimental geometry. The right inset shows the photocurrent as a function of the azimuth angle α measured for $T = 4.2$ and 35 K at fixed $B_x = +5$ T. Triangle symbols correspond to 30 nm, circle and squared symbols to 20 nm QW structures.

III. RESULTS

A. Photocurrent induced by linearly polarized/unpolarized radiation

We shall start by describing the results obtained by irradiating the sample with linearly polarized radiation which may result only in signals due to the LMPGE and excludes the CMPGE. The magnetic field induced photocurrent is studied by applying an in-plane magnetic field B_x. The observed signal varies with magnetic field strength and its sign depends on the magnetic field direction. While for the 30 nm QW sample no signal is detected at zero magnetic field, in samples with $L_W = 20$ nm QW we observed a signal at $B_x = 0$. The origin of this magnetically independent signal[39] is not within the scope of this paper and will be discussed elsewhere. In the following, we eliminate this contribution

by taking $J(|B|)$ as

$$J_y(|B|) = [J(B_x > 0) - J(B_x < 0)]/2 \qquad (1)$$

so that only magnetic field dependent effects remain.

Transverse photocurrent $J_y(|B|)$ excited by the linearly polarized radiation of low power cw laser is shown in Fig. 2 as a function of the magnetic field B_x and in the right inset in Fig. 2 as a function of the azimuth angle α for a fixed magnetic field $B_x = +5$ T. While at low temperatures the transverse photocurrent J_y comes almost all from the polarization independent offset, at higher temperature we observed a variation of the photocurrent with rotation of linear polarization ($J_y = J_1 + J_2 \cos(2\alpha)$). In the longitudinal configuration we detected only the polarization dependent photocurrent $J_x = J_3 \sin(2\alpha)$ which, like transversal partial current $J_2 \cos(2\alpha)$, contributes at higher temperatures only. The experiment reveals that, in particularly at low temperatures, the polarization dependent photocurrent contributions, $J_2 \cos(2\alpha)$ and $J_3 \sin(2\alpha)$, in our samples are substantially smaller than J_1. Thus in the following we focus on the polarization independent photocurrent J_y observed in the transverse geometry.

FIG. 3: Magnetic field dependence of J_y/P for $\lambda = 148$ μm and different temperatures. Lines are fit after Eq. (15).

The most striking observation comes from the investigation of the magnetic field dependence of the photocurrent. The general behavior of the photocurrent is that the magnitude of J_y is proportional to B_x for low magnetic fields only. At higher fields, however, the signal becomes nonlinear: with increasing B_x the sign of dJ_y/dB_x changes and, finally, the signal vanishes and for some conditions even reverses its sign. Figure 2 shows such a magnetic field dependence measured applying low power radiation of the cw laser with $P \approx 1.6$ mW. In Figs. 3 and 4 we plotted the magnetic field dependence of J_y excited by the high power radiation of the pulsed laser. The data obtained for a fixed wavelength of $\lambda = 148$ μm and various temperatures (Fig. 3) and for fixed temperature of 4.2 K but several wavelengths (Fig. 4). Figure 3 depicts that increasing the temperature reduces

FIG. 4: Dependence of the LMPGE on the magnetic field at $T = 4.2$ K for wavelengths of $\lambda = 148$ and 280 μm obtained for 20 nm QW structure. The inset shows the LMPGE for 30 nm QW sample. Lines are fit after Eq. (15).

the magnitude of the photocurrent , whereas the magnetic field $B_x \approx 6.2$ T at which the zero-crossing occurs remains almost unchanged. Measuring the temperature dependence for both low power and high power excitations we obtained that for $T < 8$ K the photocurrent is constant at fixed magnetic field and at higher temperatures rapidly decays showing close to $J \propto 1/T$ behavior (not shown). In the case of fixed temperature but increasing wavelength (see Fig. 4) the magnitude of the photocurrent increases and the zero-crossover is shifted to higher magnetic fields. Finally we note, that sweeping the magnetic field from negative to positive and back we did not observe a hysteresis.

Our experiments demonstrate that the photocurrent is dominated by a photocurrent contribution which is insensitive to the radiation polarization. Earlier studies of magneto-photocurrents demonstrated that such polarization independent photocurrents are caused by the radiation induced electron gas heating followed by the scattering asymmetry in $\boldsymbol{k}$-space, see Refs. [25,26,28]. In order to characterize the electron gas heating in our structures we investigated the THz-photoconductivity applying the same wavelengths and powers. Figure 5(a) shows the photoconductive signal excited by cw THz laser as a function of radiation power. The observed decrease of the structure conductivity with increasing THz radiation (negative photoconductivity) provides the evidence for the electron gas heating. Indeed, Hall measurements, see Fig. 1(b) and the inset in Fig. 5(b), show that a rise of temperature results in the decrease of mobility and, consequently, in the lowering of conductivity. The data for pulsed excitation, presented in Fig. 5(b), demonstrate that an increase of the radiation power by about six orders of magnitude results in a change of the relative photoconductivity $|\Delta\sigma/\sigma_0|$ by two orders of magnitude. We attribute the observed nonlinearity of the photoconductive response to nonlinear energy losses in InSb QWs at low temperature, which, consequently, cause a strongly nonlinear dependence of the electron temperature on the

absorbed energy[24]. Comparison of the data obtained at $\lambda = 148$ and $280\ \mu$m demonstrates essentially stronger electron gas heating at a longer wavelength. This observation is in a good agreement with the frequency dependence of the Drude-like absorption. Figure 5(b) shows that for radiation power of several kilowatts relative photoconductivity achieves values as high as 10^{-2} to 10^{-1}. Comparison of these values with the mobility data [see the inset in Fig. 5(b)] shows that pulsed THz radiation used here can heat up the electron gas by tens kelvin [40].

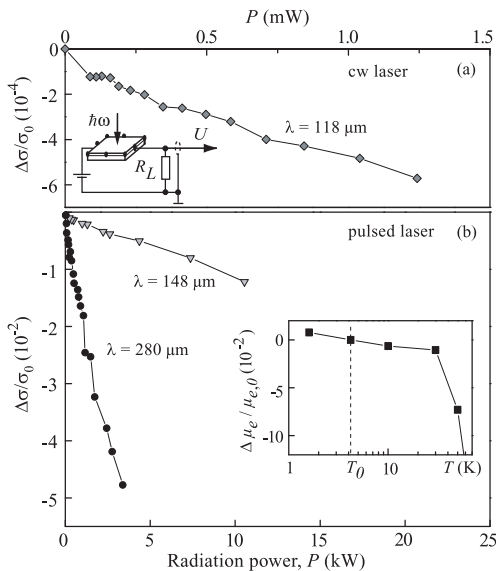

FIG. 5: Relative change in conductivity, $\Delta\sigma/\sigma_0 = (\sigma_i - \sigma_0)/\sigma_0$, in QW structure with $L_W = 20$ nm measured versus radiation power P at $T = 4.2$ K and $B = 0$. The ratio of conductivity under illumination, σ_i, and dark conductivity, σ_0, is determined from the photoconductive signals measured in the circuit sketched in the inset of the upper plate. (a) Photoconductive signal measured applying cw radiation with wavelength $\lambda = 118\ \mu$m. (b) $\Delta\sigma/\sigma_0$ measured applying pulsed laser radiation with $\lambda = 148$ and $280\ \mu$m. The inset shows a section of the temperature dependence of the relative mobility $\Delta\mu_e/\mu_{e,0}$, where $\mu_{e,0}$ is the mobility at $T_0 = 4.2$ K.

B. Photocurrent induced by circularly polarized radiation

We will now describe the results for irradiation with circularly (elliptically) polarized light which is obtained using a $\lambda/4$ plate. The ellipses on top of Fig 6 illustrate the polarization states for various angles φ. The resulting polarization state is given by the Stokes parameters[42] $S_1 = \cos^2(2\varphi)$ and $S_2 = \sin(4\varphi)/2$, describing the degree of linear polarization, and $S_3 \equiv P_{\text{circ}}$. The photocurrent detected in the transverse geometry is well described by $J_y = J_1 + (J_2/2)\cos(4\varphi)$. The photocurrent consists of polarization independent contribution, J_1, and a contribution that is proportional to the degree of linear polarization, i.e. just the same as discussed

in the previous section. In the longitudinal geometry $(J_x \parallel B_x)$, however, we observed a new contribution to the photocurrent. It manifests itself in the helicity dependence of the signal. The dependence of the photocurrent J_x on φ is shown in Fig. 6. It is well described by $J_x(\varphi) = (J_3/2)\sin(4\varphi) + J_C\sin(2\varphi) + \xi$. Here the first term is again just the contribution proportional to J_3 in the described above experiments with linearly polarized radiation. It reflects the degree of linear polarization and vanishes for circularly polarized light. The second term is proportional to the radiation helicity P_{circ}. This circular photocurrent changes its sign by switching the light helicity from -1 to $+1$. Note that the observed offset ξ is much smaller than J_3 and J_C and is subtracted from the data of Fig. 6. We will focus on circular photocurrent in the longitudinal geometry, thus we can extinguish all other possible effects by

$$J_C = [J_x(\sigma^+) - J_x(\sigma^-)]/2. \tag{2}$$

Figure 7 shows the magnetic field dependence of the circular photocurrent J_C measured in the 20 nm QW structure for different wavelengths. Similarly to the photocurrent induced by linearly polarized radiation its magnitude normalized by the radiation power substantially increases for longer wavelengths: the fact which can also naturally be attributed to the increase of the Drude-absorption. However, unlike the photocurrent induced by linearly polarized radiation (Fig. 2 - 4), the circular photocurrent remains proportional to the magnetic field B_x up to the highest field applied, $|B| = 7$ T. The same behavior has been observed in the 30 nm structure (not shown).

FIG. 6: Helicity dependence of the photocurrent J_x measured for $B_x = -6$ T and $\lambda = 280\ \mu$m with subtracted offset ξ. The inset shows the experimental geometry. The ellipses on top illustrate the polarization states for various φ.
FIG. 7: Magnetic field dependence of J_x/P for wavelengths of $\lambda = 90.5, 148$ and 280 μm at $T = 270$ K.

FIG. 8: Models of magneto-gyrotropic photogalvanic currents: (a) - spin-dependent LMPGE; (b) - orbital LMPGE.

IV. DISCUSSION

All our observations at low magnetic field exhibit the recognized MPGE behavior, which by definition is a magnetic field induced photocurrent related to the gyrotropic symmetry of the system[26]. In particular, the observed linear coupling to the magnetic field, the in-plane anisotropy of the photocurrent, as well as the polarization dependences all follow the symmetry arguments for the MPGE. The current perpendicular to the magnetic field is dominated by the polarization independent contribution (LMPGE) and is therefore driven by relaxation processes[28,41]. At the same time the longitudinal magnetic field induced photocurrent excited by circularly polarized radiation is solely governed by the photon angular momentum (CMPGE)[27]. Comparison of our data on the magnetic field induced photocurrents with that reported earlier for GaAs- and InAs-based QW structures (for review see[25]) shows that it is much stronger in InSb QWs by at least two orders of magnitude. We note that for the 30 nm QWs compared to our 20 nm QW we detected ten times larger photoresponses, see the inset in Fig. 2 and the data for $\lambda = 280$ μm in Fig. 4. While the general features of our signals are in agreement with previous results for III-V QWs, the magnetic field dependences of the LMPGE and the CMPGE in InSb-based QWs have a contradictory behavior: the LMPGE is nonlinear and the CMPGE is linear. We will now discuss separately the LMPGE and CMPGE in terms of the interplay between the spin and orbital (non-spin) related relaxation processes. We will show that this interplay results in the surprising magnetic field behavior.

A. Linear MPGE

The spin-related origin of the LMPGE is a consequence of the electron gas heating followed by spin dependent scattering[25,28,41]. The latter is due to the spin-orbit interaction in gyrotropic media, such as InSb- and GaAs-
based low-dimensional structures, which yields a scattering matrix element being proportional to $[\boldsymbol{\sigma} \times (\boldsymbol{k} + \boldsymbol{k}')]$. Here $\boldsymbol{k}$ and $\boldsymbol{k}'$ are the initial and the scattered wave vectors and $\boldsymbol{\sigma}$ is the vector composed of the Pauli matrices and only structural inversion asymmetry is assumed. This spin dependent scattering results in an asymmetric relaxation of the hot electrons shown by the different thickness of the arrows in Fig. 8(a) and causes oppositely directed electron fluxes $\boldsymbol{i}_{\pm 1/2}$ in the spin subbands. Consequently, a spin current, defined as difference between the fluxes, is given by $\boldsymbol{J}_s = 1/2(\boldsymbol{i}_{+1/2} - \boldsymbol{i}_{-1/2})$. At nonzero magnetic field, e.g., B_x, the Zeeman effect causes an equilibrium spin polarization parallel to the magnetic field and the fluxes become unbalanced due to the unequal equilibrium population of the spin subbands. The average electron spin s is equal to

$$s = \frac{1}{2} \frac{N_{+1/2} - N_{-1/2}}{N_{+1/2} + N_{-1/2}} . \quad (3)$$

Such an imbalance results in a net electric current $\boldsymbol{j}_{\text{spin}}$ given by the sum of the fluxes, $\boldsymbol{j}_{\text{spin}} = -e(\boldsymbol{i}_{+1/2} + \boldsymbol{i}_{-1/2})$, where $-e$ is the electron charge. Assuming that the fluxes $\boldsymbol{i}_{\pm 1/2}$ are proportional to the carrier densities in the spin subbands $N_{\pm 1/2}$, one obtains

$$\boldsymbol{j}_{\text{spin}} = -4es\boldsymbol{J}_s . \quad (4)$$

We note that while in the theoretical consideration the current density $\boldsymbol{j}$ is used, in the experiments the electric current $\boldsymbol{J}$ is measured which is proportional to the current density $\boldsymbol{j}$.

At low magnetic fields with the Fermi energy E_F larger than the energy of the Zeeman spin splitting, $\boldsymbol{s}$ is a linear function of magnetic field $\boldsymbol{B}$ and is given by

$$\boldsymbol{s} = -\frac{\Delta}{4E_F} \frac{\boldsymbol{B}}{B} , \quad (5)$$

where $\Delta = g^* \mu_B B$ is the energy of the Zeeman spin splitting and μ_B is the Bohr magneton. However, in the high field limit for $|\Delta| > 2E_F$ one of the spin subbands will be completely depopulated. Obviously in this case the average spin $s = \pm 1/2$ and J_y saturates.

The behavior of the spin-dependent LMPGE, $J_y \propto s$, over all magnetic fields can be obtained taking into account that in thermal equilibrium, the densities $N_{\pm 1/2}$

are determined by

$$N_{\pm 1/2} \propto \sum_{\boldsymbol{k}} \left[\exp\left(\frac{\varepsilon_{\boldsymbol{k}} \pm \Delta/2 - \mu}{k_B T_e} \right) + 1 \right]^{-1}, \qquad (6)$$

where $\varepsilon_{\boldsymbol{k}} = \hbar^2 k^2/(2m^*)$ is the kinetic energy, m^* is the effective mass, μ is the chemical potential, k_B is the Boltzmann constant, and T_e is the electron temperature. Effects on $N_{\pm 1/2}$ due to nonparabolicity of the subbands[3] will be weak compared to the Boltzmann redistribution from the Zeeman spin splitting, and are therefore ignored. Straightforward summation over the wave vector $\boldsymbol{k}$ yields

$$s = \frac{1}{2} \frac{\ln\left\{ \left[1 + \exp\left(\frac{\mu - \Delta/2}{k_B T_e} \right) \right] / \left[1 + \exp\left(\frac{\mu + \Delta/2}{k_B T_e} \right) \right] \right\}}{\ln\left\{ \left[1 + \exp\left(\frac{\mu - \Delta/2}{k_B T_e} \right) \right] \times \left[1 + \exp\left(\frac{\mu + \Delta/2}{k_B T_e} \right) \right] \right\}}. \qquad (7)$$

Equation (7) describes the average spin of two-dimensional carriers in an external magnetic field for a fixed chemical potential μ. If, instead, the carrier density $N_s = N_{+1/2} + N_{-1/2}$ like in our case is fixed, Eq. (7) should be supplemented with the following equation for the chemical potential

$$\mu = k_B T_e \ln \left[\sqrt{ \exp\left(\frac{2\pi N_s \hbar^2}{m^* k_B T_e} \right) + \cosh^2\left(\frac{\Delta}{2 k_B T_e} \right) - 1 } \right. \qquad (8)$$
$$\left. - \cosh\left(\frac{\Delta}{2 k_B T_e} \right) \right].$$

The magnetic field dependence of s given by Eq. (7) is nonlinear saturating at $|s| = 1/2$. However, the deviation from linear dependence for the degenerate electron gas occurs at rather high magnetic fields when the average spin projection is close to $\pm 1/2$. Therefore, we suggest that other effects resulting in a nonlinear magnetic field dependence of the electron spin are responsible for the observed reversal of the electric current with the field increase. As a possible origin of this effect we consider *exchange interaction* between electrons which is known to lead to a nonlinearity of the Zeeman splitting on the external magnetic field at moderate fields[11,14]. In this case the effective g^*-factor besides g_0, Landé factor at $B = 0$, contains a contribution linear in the spin polarization

$$g^* = g_0 + 2|s|g^{**}, \quad \Delta = (g_0 + 2|s|g^{**})\mu_B B, \qquad (9)$$

where $2|s|g^{**}$ is the contribution to g^*-factor caused by the exchange interaction. Equations (7) and (9) supplement each other and are to be solved together. The calculated magnetic field behavior of the average spin and, consequently, the photocurrent ($J_y \propto s$), is plotted in Fig. 9. For calculation we used $g_0 = -25$ and an effective mass $m^* = 0.02 \, m_0$ determined by magneto-transport experiments[11] and cyclotron resonance data (not shown), respectively. Figure 9(a) shows the average spin calculated for 20 nm QW structures at fixed

temperature but for various values of the exchange interaction given by the parameter g^{**}. At low temperatures, for $g^{**} = 0$ and $|\Delta| \leq 2E_F$, we obtain a linear dependence of the average electron spin on the Zeeman splitting following the well known behavior described by Eq. (5). The exchange interaction results in a superlinear magnetic field dependence of $s(B)$ so that for $g^{**} = -30$ the average spin is substantially enhanced already at a magnetic field of several Tesla. Finally for $|\Delta| > 2E_F$ one of the spin subbands will be completely depopulated and $|s| = 1/2$. Note that $g^{**} = -30$ is obtained in InSb QWs similar to our structures by magneto-transport measurements[11]. Using this value we calculated how electron temperature influences the average spin. The results are plotted in Fig. 9(b). The data shows that an increase of the temperature results in a decrease of spin polarization and reduces the nonlinearity. However, for magnetic fields below 7 T and temperatures below ≈ 130 K, used in experiments here, s remains nearly unchanged by the temperature.

FIG. 9: Average spin in 20 nm QW structures obtained by self-consistent calculations of Eqs. (7) and (9) as a function of the magnetic field. For calculation we used $g_0 = -25$ and an effective mass $m^* = 0.02 \, m_0$. Average spin calculated for (a) fixed temperature but for various values of the exchange interaction given by the parameter g^{**} indicated by numbers next to the curves; (b) fixed exchange interaction, $g^{**} = -30$ but various electron temperatures T_e.

While spin mediated relaxation can produce a nonlinear signal it cannot cause the observed sign reversal of the photocurrent. Thus we consider another known mechanism of the LMPGE based on an asymmetric relaxation due to the Lorentz force acting on heated carriers[29–31] which may provide an additional contribution to the total photocurrent. The effect is illustrated in Fig. 8(b). Similar to the spin-related MPGE, the current stems from the asymmetric energy relaxation of the hot electrons. Now, however, this asymmetry is caused by the scattering correction being linear in the wavevector $\boldsymbol{k}$ and in the magnetic field $\boldsymbol{B}$, which is allowed in gy-
FIG. 10: Model for the spin-related CMPGE. The excitation with circularly polarized light yields a spin orientation S_{0z}. An in-plane component S_y of the nonequilibrium spin is generated by the Larmor precession.

rotropic media only[29–31]. Microscopically, this term is caused by structural inversion asymmetry (SIA) and/or bulk inversion asymmetry (BIA). This process, however, is independent of the spin and the corresponding scattering rate for, e.g., SIA, is given by

$$\boldsymbol{W}_{\boldsymbol{kk'}} = W_0 + w_{\mathrm{SIA}}[\boldsymbol{B} \times (\boldsymbol{k} + \boldsymbol{k'})]_z , \qquad (10)$$

where W_0 is the field independent term and w_{SIA} is a measure of the structure inversion asymmetry. Due to magnetic field dependent scattering, transitions to positive and negative k'_y-states occur with different probabilities. Therefore hot electrons with opposite k_y have different relaxation rates in the two spin subbands. In Fig. 8(b) this difference is indicated by arrows of different thicknesses. The resulting electric current is given by

$$\boldsymbol{j}_{\mathrm{orb}} = -2e \sum_{\boldsymbol{k}} \boldsymbol{v}_{\boldsymbol{k}} f_{\boldsymbol{k}} , \qquad (11)$$

where $\boldsymbol{v}_{\boldsymbol{k}} = \hbar \boldsymbol{k}/m^*$ is the electron velocity and $f_{\boldsymbol{k}}$ is the electron distribution function. The latter is found from the Boltzmann equation

$$G_{\boldsymbol{k}} - \sum_{\boldsymbol{k'}} [\boldsymbol{W}_{\boldsymbol{kk'}} f_{\boldsymbol{k'}}(1 - f_{\boldsymbol{k}}) - W_{\boldsymbol{k'k}} f_{\boldsymbol{k}}(1 - f_{\boldsymbol{k'}})] = 0 , \qquad (12)$$

where the generation term $G_{\boldsymbol{k}}$ describes electron gas heating by radiation. Since the scattering rate (10) contains asymmetric part proportional to $w_{\mathrm{SIA}} B$, the asymmetric part of the distribution function $f_{\boldsymbol{k}}$ and, consequently, the photocurrent $\boldsymbol{j}_{\mathrm{orb}}$ are linearly coupled with the magnetic field and the degree of SIA

$$\boldsymbol{j}_{\mathrm{orb}} \propto w_{\mathrm{SIA}} B . \qquad (13)$$

We note that this dependence remains linear in the magnetic fields up to[30,31]

$$B \approx \frac{\pi^2 \hbar c}{e L_W^2} , \qquad (14)$$

which for $L_W \approx 20$ nm is about 25 T, i.e. much larger than fields used in our experiment. Here e is electron charge and c is the speed of light.

On the phenomenological level both mechanisms are described by the same equations[29–31] and the total current is given by the sum of their contributions

$$j_y = j_{\mathrm{spin}} + j_{\mathrm{orb}}. \qquad (15)$$

Taking into account only the dependence on the magnetic field given by Eqs. 4 and 13, we used for the fitting curves $j_{\mathrm{spin}} = a \cdot s(B)$ and $j_{\mathrm{orb}} = b \cdot B$, where a and b are fitting parameters. The phenomenological similarity hinders the decomposition of both terms, because the spin contribution $J_{\mathrm{spin}} \propto s$ and the orbital one $J_{\mathrm{orb}} \propto B$ behave identically under a variation of the radiation's polarization state and the orientation of the magnetic field relative to the crystallographic axes. Our above consideration shows, however, that the behavior of the photocurrent upon a variation of the magnetic field strength is different for these two mechanisms. Combining spin and non-spin mechanisms and assuming they have opposing signs we can explain the nonlinear magnetic field behavior, in particular, the reversal of the photocurrent direction. Figure 2 shows the results of calculations fitted to the experimental data obtained at low power excitation which just slightly increase the electron temperature T_e above the lattice temperature T, see Fig. 5(a). Using the lattice temperature for calculations and scaling J_{spin}- and J_{orb}- magnitudes we obtained a good agreement between experiment and the theory in the whole magnetic field range. Figures 3 and 4 demonstrate that Eq. (15) also describes well the data for the high power excitation where the electron temperature is by tens degrees larger than the lattice one, see Fig. 5(b). As discussed above, the fact that in these experiments magnetic fields below 7 T and temperatures below 120 K are used, the dependence due to the Zeeman splitting is very weak (see Fig. 9). Therefore, we obtain good agreement for both lattice temperatures and electron temperatures assumed to exceed the lattice temperature by several tens of degrees.

Calculations show that these mechanisms yield photocurrents of comparable strength. At low magnetic fields the total current is dominated by the orbital mechanism. However, even at moderate magnetic fields, the nonlinear increase of the average spin due to the exchange interaction causes an enhancement of the spin-related LMPGE which at high fields becomes the major origin. The fact that the orbital effect provides a comparable contribution to the spin-related effect is surprising, particularly when taking into account that InSb QWs are characterized by the strong spin-orbit coupling and enhanced magnetic properties. Orbital effects, however, are also enhanced in InSb QWs. The reason is the narrow gap leading to a small effective mass of electrons. As demonstrated in Ref. [30,31] the orbital current increases with a lower effective mass.

B. Circular MPGE

The signature of the CPMGE is that the signal is proportional to the radiation helicity and, consequently, reverses the sign upon switching the helicty from left to right circular polarization, see Fig. 6. In a similar approach to the LMPGE we consider the interplay between the spin and non-spin mechanisms. We firstly discuss the spin related contribution which is microscopically due to the spin galvanic effect[27]. For the geometry shown in the inset of Fig. 6 the magnetic field dependence of the CMPGE photocurrent caused by the spin-galvanic effect (see Fig. 10) is given by[27]

$$J_x \propto -\frac{\omega_L \tau_{s\perp}}{1 + (\omega_L \tau_s)^2} S_{0z} , \qquad (16)$$

where $\tau_s = \sqrt{\tau_{s\|}\tau_{s\perp}}$ and $\tau_{s\|}, \tau_{s\perp}$ are the longitudinal and transverse electron spin relaxation times, the Larmor frequency is given by $\omega_L = g^* \mu_{\rm B} B_x / \hbar$, and $S_{0z} = \tau_{s\|} \dot{S}_z$ is the steady state electron spin polarization in the absence of a magnetic field. It is seen that the photocurrent should follow the well known Hanle law: it achieves the maximum of an in-plane spin and consequently the current at $\omega_L \tau_s$ about unity and vanishes for higher magnetic fields. The spin relaxation time in our 20 nm InSb-based QW has been studied applying circularly polarized pump-probe technique yielding for liquid helium temperature $\tau_s \approx 0.1$ ps and $g^* = -45$, see[13]. Thus, the photocurrent maximum is expected for magnetic fields about 2.5 T. In our experiments, however, the current linearly rises with the magnetic field and does not exhibit any nonlinearities. This fact forces a conclusion that the spin-galvanic effect does not contribute to the CMPGE.

Microscopically, the orbital contribution to the CMPGE appears similarly to that of the LMPGE current described above[30,31]. The current is caused by the action of the Lorentz force on the orbital motion of the two-dimensional electrons in the radiation field. Under irradiation with circularly polarized light electrons perform a cyclic motion. In the system with SIA/BIA the presence of an in-plane magnetic field pointed along the

[110] or [1$\bar{1}$0] axes forces them to flow predominantly along the direction of $\boldsymbol{B}$. Note, that the circular photocurrent, sensitive to the radiation helicity sign, is generated due to a retardation between the rotating electric field of the radiation and the electron velocity. Therefore, it reaches a maximum at $\omega\tau \approx 1$ (here $\omega = 2\pi f$ is the radiation angular frequency and τ is the scattering time) and vanishes for much lower or higher frequencies. The microscopic theory of this effect is given in Ref. [30,31]. Like the orbital LMPGE, the resulting orbital current J_C is caused by the B-dependent corrections to the scattering probability, Eq. (10). For QWs with $L_W = 20$ nm it is linearly coupled with magnetic field up to B about 25 T, see Eq. (14). Thus, on the basis of the magnetic field behavior, we conclude that the CMPGE in InSb-based QWs is dominated by the orbital mechanism which is in this material enhanced due to the small energy band gap.

V. SUMMARY

Summarizing, our experiments of THz radiation induced linear and circular MPGE in InSb-based QW structures show that due to narrow energy gap, strong magnetic property and strong spin-orbit coupling the effect is substantially enhanced compared to other III-V materials. The measurements demonstrate that both spin and orbital mechanisms of the MPGE contribute to the signal yielding the current contributions of comparable strength. The observed strong nonlinear behavior of the LMPGE is caused by nonlinearity of the Zeeman spin splitting and supports recent conclusions on the high polarization dependent spin susceptibility of a two-dimensional electron gas in InSb-based QWs being much larger than observed in larger mass systems[43].

[39] In general asymmetric zinc-blende structure based QWs grown on (001) exact oriented substrates belong to the C_{2v} symmetry group. A current at $B = 0$ is not allowed for materials of this symmetry and in fact does not observed in 30 nm QW samples. Thus, the signal observed in 20 nm QW samples indicates a symmetry reduction of the investigated samples due to, e.g., mis-orientation of substrate or presence of a strain in the structures. We note that although in the 20 nm QWs structures nonzero signal at $B_x = 0$ is observed, its magnitude becomes smaller than that of magnetic field induced current even for rather low $B_x \approx 0.2$ T.

[40] We note that our estimations show that for single pulse excitation the heating of lattice is negligibly small and does not contribute to the photoconductive signal, the result which is well known for such type of measurements[24]. We also note that comparison of photoconductive data with the temperature dependence of mobility can not be directly used to determine the electron temperature, because in the second case rising of lattice temperature results in increase of number of phonons.
