ABSTRACT

The increase in worldwide greenhouse gas emissions and costs for fossil fuels are forcing fuel suppliers and engine manufacturers to consider more sustainable alternatives for powering internal combustion engines. One very promising equivalent to mineral diesel fuel is hydrotreated vegetable oil (HVO) as it is highly paraffinic and offers similar combustion characteristics. This fuel offer the potential of not requiring further engine hardware modification together with correspondingly lower exhaust gas emissions and better fuel consumption than mineral diesel.

In this paper the spray and combustion characteristics of HVO and its blends are investigated and compared with mineral diesel (European standard). Evidence of the reported reductions in NO\textsubscript{x} emissions has proven contradictory with some researchers reporting large reductions, whilst others measured no differences.

This paper reports the results from comparison of three different experimental tests methods using diesel/HVO binary fuel blends. The macroscopic spray characteristics have been investigated and quantified using a constant volume spray vessel. Engine performance and exhaust emissions have also been characterised using a HD diesel engine in its original configuration (mineral diesel fuel-ready) and then in a recalibrated configuration optimised for HVO fuel.

The results show that the engine injection control and also the fuel quality can influence the formation of NO\textsubscript{x} and particulate matter significantly. In particular a potential pilot injection proved highly influential upon whether NO\textsubscript{x} emissions were reduced or not. When optimising the fuel injection, a reduction in NO\textsubscript{x} emissions of up to 18% or reductions of PN of up to 42–66% were achieved with simultaneous savings in fuel consumption of 4.3%.

1. Introduction

Hydrotreated vegetable oil (HVO) is a highly paraffinic diesel-like biofuel, with the chemical structure \( C_nH_{2n+2} \), processed from vegetable oil by adding hydrogen in a catalytic reaction. Hydrotreated fuels are also called “renewable diesel fuels” and the term biodiesel is usually avoided since this is more conventionally used for fatty acid methyl esters (FAME) produced by transesterification [1]. HVOs are mixtures of paraffinic hydrocarbons without sulphur or aromatic contents. They are characterised by a higher cetane number (CN) and lower density than conventional mineral diesel. It has been reported that no engine modification or additional service of the engine is necessary and up to 30% of HVO can be added into European diesel fuel (EN590), and even more into American diesel fuel (ASTM D975) to still meet legislative fuel standards. Even pure HVO fuel is already being utilised for public transport, such as city buses [1]. In California, Sweden and Finland it is commercially available for other users also.

As shown in Fig. 1, in the first step, the triglyceride is hydrogenated and broken down into mono-glycerides, di-glycerides and carboxylic acids. These intermediates are then formed into \( n \)- and iso-alkanes by either hydrogenation (with no carbon removal) or decarboxylation and decarbonylation (both removing a carbon from the initial intermediate) [2]. The by-products are water, carbon monoxide, carbon dioxide as well as naphtha, which is a group of liquid hydrocarbons which could be used for heating and energy requirements. The CO and CO\textsubscript{2} can react further to produce methane, another useful by-product. In the presence of a zeolite catalyst [3], reaction temperatures and pressures are between 300 and 360 °C and 50–180 bar pressure, respectively. The composition of the products to their desired state is dependent on the above reaction temperatures.

The first commercial scale HVO plant with a 170,000 ton/year capacity was built in the summer 2007 at Neste Oil’s Porvoo oil refinery in Finland [1]. Two years later, Neste started a second plant with the same capacity. In 2010 and 2011 two large scale plants in Rotterdam and Singapore with an annual capacity of 800,000 ton were commissioned. Currently HVO plants are mainly integrated into oil refinery plants, but companies have started developing larger stand-alone units around the world for large-scale production [4]. The costs of producing HVO are in some studies stipulated to be about 50% of the transesterification processing costs [5]. Kalnes, et al. however, stated that the overall economics will depend on feedstock costs and by-product revenues [6]. Sunde, et al. reported in their studies that HVO made from waste or by-products outperforms FAMEs (fatty acid methyl ester) and Btl. (bio-mass-to-liquid) in respect to costs and environmental life cycle impacts [5]. However, feedstock availability and logistics are currently limiting factors and other raw materials must be used. HVO has lower viscosities, lower cloud points and therefore better storage and cold flow properties than FAMEs. Also the relatively high heating value and CN makes HVO a very high-quality fuel for potential utilisation in the transportation sector. Compared to conventional biodiesel the natural lubricity of HVO is poorer and additives have to be used to increase lubrication properties [7].

Some researchers have tested HVO on different engines to gain an understanding of its combustion and exhaust formation behaviour. Kuronen, et al. tested neat HVO on two heavy duty engines and two city buses and compared the results with EN 590 diesel fuel [8]. For HVO, the particulate mass (PM) was reduced between 28 and 46%, NO\textsubscript{x} was reduced by 7–14% and THC and CO emissions decreased by 48% and 5–78%, respectively. In a later study, they used a 6 cylinder 8.4 litre DI engine at several speeds and loads and carried out an injection timing sweep [1]. They found that by retarding the injection, the smoke- NO\textsubscript{x} trade-offs shifted towards higher smoke numbers and lower NO\textsubscript{x} values. Also, retarding the injection resulted in higher bsfc (brake specific fuel consumption), but much lower NO\textsubscript{x} emissions. They concluded that a clear reduction in NO\textsubscript{x} and smoke emissions as well as fuel consumption (mass-based), but higher volumetric fuel consumption was due to the lower fuel density. Pflaum, et al. investigated emission formation of neat HVO and mineral diesel in a CI 2 litre four cylinder test engine and on a chassis dynamometer test [9]. Their results revealed that HVO has the potential to reduce PM, THC and CO emissions up to 50% as it is free of aromatic compounds. The NO\textsubscript{x} emissions, however, only showed a slight reduction compared to fossil diesel. Rantanen, et al. tested several HVO blends (5, 15, 20 and 85 vol%) and compared them with conventional diesel [10]. They pointed out that both regulated and non-regulated emissions decreased with increasing HVO ratios. However, a clear reduction of NO\textsubscript{x} was not observed. Similar results have been found by Kim, et al. testing HVO and iso-HVO in a light duty diesel engine and no significant differences in NO\textsubscript{x} are observed when HVO blend ratio was increased [11]. A study has been carried out by Toyota investigating the effect of single and multi-injection with HVO and EN590 diesel and they found out that with a single injection NO\textsubscript{x} emissions are reduced up to about 10% with HVO, while with a pilot injection no significant reductions are found [12]. The conclusion was that with a pilot injection, the start of the main fuel ignition is very similar with HVO and mineral diesel and the heat release curves were identical.

Very few papers related to spray characteristics have been published. Hulkkonen, et al. compared the macroscopic spray characteristics of HVO and mineral diesel [13]. An injector with two different nozzle diameters of 0.08 and 0.12 mm in a common rail fuel system with rail pressures of 450, 1000 and 1980 bar were used. They concluded that neither the type of fuel, nor the orifice diameter had an effect on the spray penetration. They further found out that the cone angle of HVO is greater than that of diesel, probably due to lower viscosity of HVO. The spray angle also increased with a larger orifice diameter, but diminished with higher injection pressures. Finally they concluded that the macroscopic spray characteristics of HVO are similar to GtL (gas-to-liquid). The effect of pure HVO on macroscopic spray parameters in a DI engine were studied by Sugiyaama, et al. [12]. Their results revealed that the Sauter mean diameter, spray penetration and spray angle were similar for conventional diesel and HVO. Chen, et al. investigated the microscopic and macroscopic spray behaviour of HVO and other biofuels and concluded that HVO has a much smaller SMD than diesel and that the effect of injection pressure on spray angle was not obvious for all tested fuels [14]. Overall, the amount of research conducted on HVO is small despite HVO being a very promising future fuel. In reviewing the literature, it was concluded that the results of HVO, such as exhaust emission and spray characteristics are heavily dependent on the B0 benchmark fuel and the injection conditions used in the study. Whilst almost all studies the properties of the benchmark fuel were all within the EN590 limits, the differences in viscosity, CN and aromatics content all varied significantly and thus affected the results accordingly. In this work, the macroscopic spray characteristics, engine test bench performance and injection recalibration has been carried out with neat HVO and its blends benchmarked with the same reference fuel. The B0 fuel for blending and referencing was supplied by a well-known fuel supplier specially used for referencing purposes. The novelty of this study is the holistic investigation of spray and combustion analysis for a heavy-duty application using HVO and its blends.

2. Experimental setup and procedure

2.1. Constant volume vessel

A medium pressure, high temperature combustion vessel was used to investigate the spray and combustion characteristics using a high-speed direct photography technique. The vessel is made of Inconel alloy and is resistant against corrosion and oxidation and suited for extreme
environments and can be subjected to pressure of 100 bar and temperatures of up to 500 K. The constant volume vessel (CVV) has four optical accessible windows with 100 mm viewing size and further consists of an external 4.5 kW ceramic band heater.

The fuel injection system contains an air-driven high pressure fuel pump, where the fuel can be pressurised and stored in a common rail up to 1800 bar. A standard Bosch solenoid injector with a 0.16 mm single-hole nozzle was mounted onto the vessel and can be triggered using an external solenoid driving box. A PHANTOM V710 monochrome charge-coupled device (CCD) camera captured the spray images with a resolution of 256 × 256 pixels, a capturing speed of 70,000 frames per second (fps) and an exposure time of 5 ns. The camera was synchronised with the injector by using the same triggering signal. A Nikon AF-S Nikkor lens with a focal length of 70–200 mm and a maximum aperture of f/2.8 was attached to the camera. A 500 W xenon light source on the opposite window ensures constant background light for the camera. The background pressure and temperature of the vessel is monitored and controlled by a control panel supplied by the vessel manufacturer. The CVV set up including high pressure fuel system and optical diagnostic devices are illustrated in Fig. 2.

After the experimental data were recorded, a MATLAB program was used to post-process the results. For the image processing one image was loaded into the program to set the processing conditions. For this the image was rotated in a position where the spray is vertical having the nozzle at the top. In the second and third stage the image was cropped to remove the edge of the visual field and converted to a binary image. After that the image was thresholded to create distinct boundaries to the spray plume ensuring the exact points for the parameter measurement to take place. To eliminate any unwanted background noise a mask was created by subtracting a blank image from the spray images with the same rotation and thresholding conditions. This program was developed to automatically measure cone angle, penetration length and spray area of consecutive images of the spray. Fig. 3 illustrated the two main spray characteristics, cone angle and penetration length, measured by the program. The “Spray Tip Penetration Length” is defined as the axial distance from the nozzle exit to the tip of the spray.

The “Cone Angle” was defined here as the angle formed by two tangential lines touching the outer boundaries of the spray on either side and joining together at the nozzle exit. The cone angle was determined by measuring the angle between nozzle exit and the first and last pixel of each row and obtaining the observed average. The spray area is defined as the area covered by the fuel plume at chamber conditions. To calculate the spray area the binary image (with the same threshold limit as for the penetration and cone angle) was used to sum up all black pixel within the spray plume. The principle is illustrated in Fig.4 for the three measurements, penetration distance, cone angle and surface area.

A single-hole nozzle with an orifice diameter of 0.16 mm was selected for the study. The vessel was filled with compressed nitrogen (N₂), heated up to 100 °C and pressurised to 70 bar resulting in a chamber density of approximately 65.5 kg/m³. The common rail pressure was set to 1800 bar and an injection duration of 0.6 ms was
selected. The chamber density, rail pressure and injection duration have been chosen specifically as they are representing the injection conditions at the end of the compression stroke in the HD diesel engine used in this study. The ten injection events were studies per test point each with around 70 images obtained within 1 ms after the start of injection. For all 700 images, the spray penetration, spray cone angle and spray surface area were determined using the custom algorithm written in MATLAB and described above.

The fuel quantity per injection stroke has been measured for each fuel by injecting 1000 times into a small container and weighing it.

2.2. Engine test bed

The engine, which was built and used in this research, is a four-cylinder Cummins ISB Euro V heavy duty, direct injection, four-stroke diesel engine with a high pressure common rail fuel system. The common rail system has a maximum pressure of 1800 bar and is connected to solenoid fuel injectors. The engine is equipped with a waste gate turbocharger and an air to water intercooler. The engine has a rated power output of 155 kW with a maximum torque level of 760 Nm between 1400 and 1800 rpm and is connected to an eddy-current W230 dynamometer to control torque and speed of the engine to within ± 1 Nm and ± 10 rpm respectively. The displacement volume is 4.5 L with a bore diameter of 107 mm and a stroke length of 124 mm. The test rig did not include an EGR or after-treatment system.

The exhaust gas is connected to a Horiba MEXA-1600D gas analyser to measure NOx, CO, CO2, O2 and HC emissions, accurate to within ± 1%. In the analyser, the NOx is measured using a chemiluminescence detector (CLD), HC with a flame ionisation detector (FID), CO/CO2 with a non-dispersive infra-red analyser (NDIR) and O2 with the magnetic-pneumatic method (MPD) [16]. A Horiba MEXA-1000 SPCS particle counter will be used to count the particle numbers in real time using Laser Based Condensation Particle Counting (CPC), accurate to within ± 10% [17].

For combustion analysis, an AVL water-cooled, high-speed pressure transducer QC34C (± 0.2 bar) is mounted in cylinder #3 to record the in-cylinder pressure. An optical crank angle encoder 365C supplied by AVL is mounted at the free end of the crank shaft to provide crank-angle based timing information for the pressure transducer. From the pressure and crank angle data, the indicated mean effective pressure (imep), heat release profile and combustion duration (defined as HR10 to HR90) can be derived. The pressure sensor signal is converted from an electrical charge into a proportional voltage signal and amplified through an AVL 1-channel charge amplifier and recorded through a high-speed NI data acquisition card PCI-6251. An external fuel conditioning system has been installed to cool down the fuel return flow...
and measure the bsfc using an integrated Coriolis flow meter, which has a maximum measured error of ± 0.15%. A schematic diagram of the engine setup is shown in Fig. 5.

For the engine tests, the European Stationary Cycle (ESC) was used and it is illustrated in Fig. 6. At each test point, the emissions have been recorded over a period of 120 s and the crank-angle based in-cylinder pressure was logged over a period of 300 cycles.

The test fuels for the work were supplied in blends of HVO10, HVO20, HVO50 and HVO100. A comprehensive analysis of the fuel properties was carried out. The main fuel properties are illustrated in Table 1.

3. Results and discussion

3.1. Spray test results

3.1.1. Spray penetration

The averaged spray penetration for B0, HVO100 and HVO50 are plotted in Fig. 7 (top). The graph can be divided into three stages. The initial part shows a linear phase, which is identical for all three fuels. In the second phase the injection advances as a function of square root over time. In the third phase, the injection event itself has stopped after 0.6 ms and the spray plume continues travelling with at a similar speed across the chamber. The start of injection has been referenced to the origin as there were slight differences in the visual start of injection. The spray penetration at the start is very similar for all fuels until the curve for HVO50 and HVO100 gradually starts to deviate from the B0 curve. The overall lower spray penetration curve for HVO has also been observed by other researchers [13,14]. The lower fuel density of HVO as well as the smaller SMD are the most likely sources for the lower penetration length in a high density chamber as they carry less momentum than heavier and larger droplets.

3.1.2. Spray cone angle

Fig. 7 (middle) shows the evolution of the cone angle of the three fuels. The spray angle of all fuels is relatively constant between 21° and 25° during the full injection duration. In particular, the initial phase shows very constant spray angles for all fuels until the spray breakup point is reached. After that, the spray angle is widest for HVO100 followed by HVO50. Similar observations were made by other researchers [13,19]. Kitano et al. explained the wider cone angle and smaller SMD
with GtL, which is very similar to HVO, was related to the lower viscosity [19]. Nevertheless in this study the viscosity of HVO and B0 were almost identical, and the smaller SMD and therefore wider cone angle are also affected by the lower fuel density [20].

The wider cone angle, but shorter penetration suggest that HVO is probably more evenly distributed in the chamber and together with the lower SMD (and therefore faster evaporation rate), the fuel-air mixing is probably more evenly distributed in the chamber and together with the lower fuel density and higher heating value of HVO, the premix combustion phase will take place more rapidly, potentially resulting in issues with engine noise and NO\textsubscript{x} emissions. As noted large reductions in NO\textsubscript{x} emissions did decrease with increasing concentrations of HVO. In terms of NO\textsubscript{x} emissions, the largest reduction was achieved with HVO50 fuel emitting 2.1% less NO\textsubscript{x} than the benchmark. The highest increase in NO\textsubscript{x} was observed with HVO20 fuel of 1.5% above benchmark. PN reductions were highest at HVO20 with 17% followed by HVO100 with 14% compared to B0 benchmark.

With HVO20 fuel, the NO\textsubscript{x} emissions were observed to be greater than the trend whereas the PN emissions were reduced simultaneously. This observation was investigated further and a combustion analysis showed that at HVO20, the SOC was about 0.5 CAD later compared to the SOC at HVO10, HVOS0 and HVO100. With more time for the fuel-air mixture to premix, higher NO\textsubscript{x} and lower PN might be expected. Also the end of combustion (CA90) is relatively early and the diffusion combustion phase is reduced for this particular point. The combustion duration versus blend ratio has been plotted in Fig. 10 and a correlation between combustion duration and particulate emissions can be drawn. The specific CO and THC emissions are shown in Fig. 11. Both reduced with increasing HVO blend with the maximum reduction of 29% for CO and 61% in THC. The reduction in CO was attributed to the better fuel-air mixing observed during the spray tests thus minimising any overly fuel-rich zones. In addition, the absence of aromatics would also be expected to affect CO formation as they require higher temperatures to break down and oxidise. The THC are reduced due to lower distillation curve of HVO providing a more complete evaporation at injection and therefore better combustion, furthermore the lack of

3.2. Unmodified engine test comparison

The objective here was to quantify how the engine performance and exhaust gas emissions might respond to the different fuel blends in the event that the mineral diesel fuel was simply replaced by an end-user for HVO and HVO/mineral diesel blends.

3.2.1. Engine performance

The average power output at full load and the fuel consumption across the whole test cycle is shown in Fig. 8. The error bars represent the standard deviation around the mean value. In general, the reduction in power and specific fuel consumption (thermal efficiency) follows a linear trend. With increasing HVO blends, the engine power is reduced marginally from 135.6 kW to 135 kW due to the lower fuel density and therefore lower volumetric heating value. However, the differences are very small and in practice would not be noticeable by an end-user, it can therefore be concluded that full power can be achieved even with HVO100. Fuel consumption reduces with increasing blend ratio from 217.5 g/kWh to 212.5 g/kWh resulting in fuel savings of 2.3% due to a higher thermal efficiency. The reduction in fuel consumption corresponds to the higher mass-based heating value (2.4%) of HVO.

3.2.2. Engine exhaust emissions

Fig. 9 shows the specific NO\textsubscript{x} and particulate number (PN) emissions over the whole ESC cycle with increased HVO fractions. The NO\textsubscript{x} emissions were not affected by increased blend ratios, however the PN emissions did decrease with increasing concentrations of HVO. The specific NO\textsubscript{x} emissions, the largest reduction was achieved with HVO50 fuel emitting 2.1% less NO\textsubscript{x} than the benchmark. The highest increase in NO\textsubscript{x} was observed with HVO20 fuel of 1.5% above benchmark. PN reductions were highest at HVO20 with 17% followed by HVO100 with 14% compared to B0 benchmark.

With HVO20 fuel, the NO\textsubscript{x} emissions were observed to be greater than the trend whereas the PN emissions were reduced simultaneously. This observation was investigated further and a combustion analysis showed that at HVO20, the SOC was about 0.5 CAD later compared to the SOC at HVO10, HVOS0 and HVO100. With more time for the fuel-air mixture to premix, higher NO\textsubscript{x} and lower PN might be expected. Also the end of combustion (CA90) is relatively early and the diffusion combustion phase is reduced for this particular point. The combustion duration versus blend ratio has been plotted in Fig. 10 and a correlation between combustion duration and particulate emissions can be drawn. The specific CO and THC emissions are shown in Fig. 11. Both reduced with increasing HVO blend with the maximum reduction of 29% for CO and 61% in THC. The reduction in CO was attributed to the better fuel-air mixing observed during the spray tests thus minimising any overly fuel-rich zones. In addition, the absence of aromatics would also be expected to affect CO formation as they require higher temperatures to break down and oxidise. The THC are reduced due to lower distillation curve of HVO providing a more complete evaporation at injection and therefore better combustion, furthermore the lack of
aromatics content would also be expected to reduce hydrocarbon emissions in the exhaust gas.

### 3.2.3. Combustion analysis

To analyse the combustion of HVO in comparison with mineral diesel, the heat release rate (HRR) of various test points within the ESC cycle (Fig. 6) has been selected as representative to provide more insight into the combustion heat release rates.

Fig. 12 shows the HRR of B0 and HVO at test point #2 at engine speed A (1490 rpm) and full load (730 Nm). The shape of the HRR curve is very similar for B0 and HVO and the difference in the higher CN of HVO has no observable effect on ignition delay, neither for the pilot nor main injection events. Schaberg et al. reported that the differences in ignition delay (ID) between a high-CN fuel and a low CN fuel diminishes with higher in-cylinder pressure and temperature [21]. Fig. 13 shows the difference in ID as a function of the internal gas temperature and pressure, which indicates that a difference in CN is more effective at lower engine loads. Whilst the presented diagram was generated for GtL fuel, it is also valid for HVO as many of its fuel properties are identical and differences in their chemical structure are considered small [1,8–10,22,23].

At point #2, NOx emissions proved constant and PN is reduced by 7% and 14% for HVO50 and HVO100, respectively. This shows that the reductions in PN were not due to an earlier SOC or shorter ID, but were due to an absence of aromatics and possibly the lower distillation curve of HVO.

Fig. 14 shows the HRR at the same speed but low load of 200 Nm and the effect of CN is seen for pilot injection. However, the ID for the main injection is nearly zero for all fuels showing that the pilot injection has raised the internal gas temperature to a high enough value that the CN does not affect the main combustion phase. This explains why the NOx emissions are not reduced significantly on this engine, but can still be reduced in other engines with alternative control strategies. This is in agreement with the work carried out by Toyota showing that NOx emissions are reduced with HVO when a single injection was used, but NOx emissions are unchanged once a pilot injection was added [12].

The NOx emissions are again fairly constant for the three different fuels and PN reduces by 9.9% and 24.5% with HVO50 and HVO100, respectively.

Fig. 15 shows the HRR at 1855 rpm and 730 Nm (point #8). At higher engine speed, the higher CN of HVO leads to shorter ID at both pilot and main injection. The NOx increased slightly by 6.7% and 5% for HVO100 and HVO50, respectively. This is potentially due to the slightly earlier increase in heat release for the main combustion and higher peak pressures and temperatures for HVO50 and HVO100. The PN emissions are reduced by 3.7% and 8%, respectively.

Finally, the heat release rate at 1855 rpm and 200 Nm (point #9) is shown in Fig. 16. The NOx emissions remained unchanged, except that the HVO50 series seems to have lower NOx emissions in general, which itself is a potentially a result of the late SOC and combustion duration presented in Fig.10 and described above. The PN emissions have been reduced with HVO100 and HVO50 by 6% and 21%, respectively and therefore similar to 1490 rpm and low load in Fig.14.

The engine employed in this study had an average ID (ignition delay) of 3.72 CAD for HVO100 and 5.25 CAD for B0. At average speed of 1855 rpm this is equivalent to an ID of 0.33 ms and 0.47 ms, respectively. However, the ID time is only relevant for at the pilot injection phase and no difference in ID was observed for the main injection. Therefore, the increased CN had no observable effect on the NOx reduction when a pilot injection took place and the internal gas
temperature is already very high. Basically, the pilot injection is compensating for the low CN in some point and therefore the benefit of high CN of HVO cannot develop its full potential. Hartikka et al. explained the lower absolute emission reductions with HVO with more recent engines, such as EURO IV, V and VI, due to the aftertreatment system and the more precise and complex control strategy of the engine [22]. As new aftertreatment is equipped to this test engine, the addition of the pilot injection is the main contributor to the lower emissions reductions. Also the quality of the benchmark fuel itself will play a major effect in the reduction potential of HVO. Especially the aromatics content and the CN of mineral diesel can vary significantly and affect the any emissions benchmark.

The lower adiabatic flame temperature in the absence of aromatics is often used as an explanation for lower NOx emissions of HVO [13,21,22,24]. It is more likely that the injection control strategy of the engine is also very important for differences in NOx emissions. This is in agreement with the statement by Hartikka et al. that higher NOx reductions have often been found in older engines, which are equipped with a more simple injection strategy [22]. Also passenger vehicles fuelled with HVO show less NOx improvement with HVO than heavy duty engines, which could easily be associated with employing a pilot injection strategy in the engines used in those passenger cars [25].
3.3. Engine recalibration options

As it was concluded that emissions are most directly influenced by the injection strategy of the engine itself, specific test points over the ESC cycle were chosen for re-calibration by changing the start of injection (SOI) and rail pressure (RP) with HVO100 fuel.

The three points #7, #3 and #4 presented in Fig. 6 have been chosen for optimisation and a Design of Experiment (DoE) according to Fig. 17 has been developed around the original manufacturer’s configuration. Each optimisation was carried out three times and offered sufficient repeatability in terms of fuel consumption, exhaust emissions and in-cylinder pressure data.

Figs. 18 and 19 illustrate the NO\textsubscript{x} and PN emissions of HVO for the three different test points in relation to the SOI and RP. While the NO\textsubscript{x} emissions show a linear trend with changes in SOI and RP, the PN emissions follow a quadratic trend for all test points. This is in agreement with the study of Su et al. who investigated the effect of injection pressure on spray SMD and particulate emissions. They found that the correlation between injection pressure and SMD is linear, but the effect of SMD on particulate emissions is non-linear and seems to follow a quadratic trend [26]. The observed NO\textsubscript{x} emissions increased with advanced injection as the peak pressure was closer to TDC and therefore cylinder temperature is increased. Also, the NO\textsubscript{x} emissions reduced with reducing rail pressure. This can be explained by the lower kinetic energy available and therefore smaller droplet size distribution of the fuel. This decelerates fuel atomisation and evaporation rates, and the heat release from premix combustion phase is reduced. However, the reduction in NO\textsubscript{x} due to the RP is small.

At point 7 (low engine load) the PN emissions increased with retarding injection timing. When increasing the engine speed and load (point #3) this is still the case, but at a much lower magnitude. At higher loads, the trend falls to a reduction in PN emissions with retarded injection. This is an interesting observation and the combustion duration follows exactly the same trend resulting in longer combustion at low load when injection is retarded, but longer duration at high load.

![Fig. 17. Design of experiment for engine recalibration.](image)

![Fig. 18. NO\textsubscript{x} emissions as function of SOI and RP for all test points #3, #4 and #7.](image)

![Fig. 19. PN emissions as function of SOI and RP.](image)
when injection is advanced. The PN emissions were increased significantly when rail pressure is reduced due to the higher SMD at lower injection pressure and a reduced degree of mixing, therefore resulting in higher particulate emissions. As the benefit of reducing rail pressure in terms of NO\textsubscript{x} is small, but the penalty on PN emissions is huge, it can already been concluded that reducing rail pressure is not an effective strategy for recalibrating the engine control system.

A NO\textsubscript{x}, PN and fuel consumption model has been established for various rail pressure and SOI at all three test points. In line with the observations/methods of Su et al. [26], for the NO\textsubscript{x} emissions and fuel consumption a linear correlation and for the PN emissions a quadratic correlation has been employed. An example of the NO\textsubscript{x} and PN model as a contour plot are shown in Figs. 20 and 21 for test point #4.

With these models, a NO\textsubscript{x}-PN trade-off curve has been generated.
showing the lowest PN emissions at each NOx value. At each of these points, the corresponding fuel consumption has been calculated. The trade-off curves for all three points are illustrated in Fig. 22 including their original control settings and the benchmark emission of B0 EN590 fuel.

As mentioned previously, using the RP to reduce as the penalty in PN is not advisable as it exceeds the benefits of reducing NOx. Increasing the RP could be advantageous, but due to hardware restrictions this was not technically possible in this study. Thus, the trade-off curve was considered only at maximum rail pressure and runs from advanced injection to retarded injection were carried out. The highest reductions in NOx can be achieved by retarding the SOI by 3.0 CAD and the reduction potential is 16.9%, 18.4% and 17.9% for point #7, #3 and #4, respectively. The corresponding PN emissions are 623%, 174% and 0%, respectively, higher than the B0 benchmark. The lowest PN emissions can be achieved when advancing the injection timing by 3.0 CAD and reductions of 66% and 42% are possible for point #7 and #3. The corresponding NOx emissions are 10.8% and 2.3% higher, respectively. At point #4, a distinctive minimum is found at the lowest PN emissions are found when retarding the injection by 2.7 CAD. At this point the PN emissions can be reduced by 36% and NOx emissions by 9.9%. The brake specific fuel consumption follows a linear trend towards advanced injection. The highest savings can therefore be achieved at advanced injection with a lower fuel consumption compared to B0 of 2%, 3.5% and 4.3% for point #7, #3 and #4, respectively.

4. Conclusions

Vast differences in exhaust emissions using HVO compared to mineral diesel have been observed in recent papers. One of the main reasons for this was the fuel properties of the benchmark EN590 mineral diesel fuels themselves, which can change significantly, in particular with aromatics content, viscosity and CN. All these parameters will affect the engine-out NOx and particulate emissions. In addition, the engine control strategy is different for every engine and it was concluded that the injection control strategy is responsible for the main differences in exhaust gas emissions. The following further conclusions have been made:

- The penetration distance of HVO is shorter than mineral diesel due to lower SMD and fuel density carrying less momentum during the injection.
- The cone angle of HVO is wider than B0 for the same reasons as the penetration.
- The fuel-air mixing of HVO is better than B0 due to larger cone angle and lower local fuel concentration in the chamber. This will affect the premix combustion and NOx emissions. The shorter ID of HVO might counteract this effect in some engines.
- No significant power loss appears with HVO. The bsfc can be reduced by up to 2.3% using neat HVO. The corresponding mass-based heating value is 2.4%.
- No reductions in NOx emissions have been observed, but a PN emissions have been reduced by 14% with increasing HVO blends.
- CO and THC emissions are reduced with increasing HVO blend due to better fuel-air mixture, absence of aromatics and lower distillation curve.
- The shape of the HRR is very similar for B0 and HVO for all test points. The ID is only really affecting the pilot combustion, but the high internal gas temperature at the point of main injection diminishes the effect of higher CN.
- Reducing rail pressure when recalibrating the engine is not beneficial as particulate number is increasing rapidly while the reduction in NOx emissions in relatively low. When recalibrating the ECU the rail pressure should only be increased (if physically possible) and SOI retarded.
- NOx emissions follow a linear trend when SOI and RP are changed. For PN emissions however a quadratic trend has been found when SOI and RP are changed.
- Max NOx reductions of around 18% with severe penalty in PN when retarding injection fully.
- Max PN reductions of 42–66% when advancing injection fully. At high load a distinctive minimum provides maximum NOx emissions in relatively low. When recalibrating the ECU the rail pressure should only be increased (if physically possible) and SOI retarded.
- Fuel consumption can be reduced by up to 4.3% below EN590 benchmark.
